n = Number of rats in each group; DEX = dexamethasone-treated, 100 μg/rat/twice daily; Progesterone = 10 mg/rat/twice daily; R 5020 = 5 mg/rat/twice daily. RU 486 was given once at 10 mg/kg body weight.

*Significant differences ($p < 0.05$) between control and treated groups.

effects of progesterone, to maintain pregnancy, may be the selective repression of the genome that regulates the expression of gap junctions between myometrial cells.[4]

There is considerable evidence that RU 486 binds to the progesterone receptor with an affinity superior to progesterone and prevents the action of the hormone at the genomic level.[1] The progesterone antagonist prevents the transcription of several progesterone-dependent proteins in some tissues.[1, 11] In this study, however, the antihormone appears to block the suppressive effects of progesterone by inhibiting the action of it at the receptor level. The antihormone's effects were not mediated through changes in plasma levels of either progesterone or estradiol, which are thought to reflect tissue concentrations, since there were no alterations in these before delivery (Table I). The decline in progesterone and estradiol at 48 hours is probably a consequence of decreased synthesis as a result of delivery.

The mechanism for the maintenance of uterine quiescence during pregnancy and the initiation of labor contractions at term in any species has never been clearly established. It is recognized that either a change in progesterone, changes in progesterone to estrogen ratios, or changes in their receptors may trigger events leading to labor in many species.[2, 5, 6, 12] The fact that RU 486 effectively stimulates labor in all species including humans[1] supports the hypothesis[2] that progesterone plays a role in the maintenance of pregnancy in all species.

Gap junctions are present between myometrial cells in large numbers during term and preterm labor in rats, humans, and other species.[3, 5] Gap junctions are membrane proteins that provide channels between the interior of cells.[13] Their presence in the myometrium is accompanied by and thought to be necessary for the synchronized and coordinated contractions of labor when the muscle cells are better coupled electrically and metabolically.[14, 15] There is much evidence to suggest that myometrial gap junction proteins are the product of a genome that is stimulated by estrogen and inhibited by progesterone.[3, 5, 6, 16] In addition, studies show that steroid hormones may similarly control the synthesis of receptors for uterine stimulants.[17] The results of the present study support these conclusions and demonstrate that progesterone and its receptors may regulate (i.e., inhibit) the synthesis of specific gene products required for labor.

The gap junction areas (Fig. 1, *B*) found in this study after RU 486 treatment are higher (at 24 and 30 but not at 48 hours) than those normally observed in the rat myometrium during both spontaneous delivery at term[4, 5, 15] and preterm delivery after ovariectomy.[18] Thus an inhibition of progesterone action appears to have greater efficacy than gradual withdrawal of the hormone. However, the delivery of the fetuses is more prolonged (Fig. 1, *A*) than observed at term, and this may indicate that the uterus has not yet developed sufficiently or that there is an inadequate stimulus for contractility. In this regard, it should be noted that RU 486 treatment in combination with uterine stimulants increase the success rate of delivery in women.[1] Perhaps after RU 486 treatment, the myometrium is prepared for labor with gap junctions and appropriate receptors for stimulants but lacks the necessary stimulation provided by oxytocin or excitatory prostaglandins.

The increase in gap junction area precedes the delivery of the fetuses (Fig. 1, *A* and *B*), and gap junction values are highest during periods (at 24 and 30 hours) when the greatest proportion of fetuses (about 70%) are delivered. These data are similar to results obtained during spontaneous delivery at term in rats.[3, 4] The mean area of gap junctions noted at 48 hours is lower than that found at 24 and 36 hours but still as high as that during normal term parturition in rats.[4]

RU 486 also binds to the glucocorticoid receptor and produces antiglucocorticoid action in high doses.[1] However, our study shows that dexamethasone has no effect

on either the RU 486-induced delivery or the development of gap junctions. These results suggest that the antiglucocorticoid effect of RU 486 is not important for the interruption of pregnancy, which agrees with previous proposals.[1] In contrast R 5020 but not progesterone blocked the action of RU 486 on both delivery and gap junctions, which supports the conclusions that the antihormone's effects are mediated through the progesterone receptor. The reason that progesterone is ineffectual but R 5020 blocks the action of RU 486 effects may be explained because of the higher affinity of the R 5020 compound for the progesterone receptor.[19]

In summary, our study suggests that progesterone may normally suppress myometrial activity and thus maintain pregnancy in rats by inhibiting a genome that controls the synthesis of gap junction proteins. Whether progesterone has a similar influence on the human myometrium remains to be resolved. However, the antiprogesterone RU 486 is also highly effective in interrupting pregnancy in women even in advanced stages,[20] and gap junctions are also present in large numbers in the human myometrium during term and preterm delivery.[4] Although these results do not preclude different control systems, they may indicate that similar mechanisms exist in humans even though the site of synthesis of progesterone during pregnancy (placenta versus ovary) is different in humans and rodents. The use of RU 486 has helped demonstrate that progesterone is required for the maintenance of both early and late stages of pregnancy in women.

We thank Debbie Merrett and Elaine Bourreau for technical assistance and Dr. D. Philibert and Roussel Uclaf for valuable discussion.

The pharmacokinetic characteristics of the antiemetic drug metoclopramide and the antihistamine diphenhydramine have been determined in a chronically catheterized pregnant sheep preparation. Metoclopramide and diphenhydramine were administered by separate maternal and fetal intravenous infusions to a steady state as well as by maternal intravenous bolus dosing. Drug concentrations in the maternal and fetal plasma and the amniotic and tracheal fluids were measured by means of capillary gas-liquid chromatographic assay techniques. Both metoclopramide and diphenhydramine were excreted into tracheal fluid in substantial quantities. Tracheal metoclopramide concentrations were found to exceed fetal plasma levels by about fifteenfold while diphenhydramine attained maximal excretion in tracheal fluid of about five times that seen in fetal plasma. Drug levels were observed to accumulate slowly in amniotic fluid and eventually to exceed tracheal concentrations. The markedly elevated concentrations of these drugs in fetal lung fluid suggests that the fetal lung may be an important route of drug distribution, elimination, and excretion. (AM J OBSTET GYNECOL 1987;157:1286-91.)

Key words: Metoclopramide, diphenhydramine, placental transfer, tracheal fluid, amniotic fluid

There are numerous reports of the pharmacokinetic behavior of drugs in the fetus, conducted either in man or in animal species.[1] Most studies have concentrated on measurement of drug concentrations in the maternal and fetal vascular compartments, with fewer investigations also examining drug levels in fetal urine and/or the amniotic fluid. One potential route of drug excretion from the fetus that does not appear to have been studied is via fluid secreted from the fetal lung. Such fluid production occurs at a rate of approximately 4 ml/kg · hr in the fetal lamb,[2] with the fluid being either secreted into the amniotic cavity or swallowed.[2] The fluid appears to be formed primarily as a consequence of active chloride transport from plasma across the pulmonary epithelium.[3] In some respects the fluid resembles an ultrafiltrate of plasma, particularly in regard to low protein concentrations. However, the plasma/lung concentration ratios for several electrolytes differ substantially from those expected in a true ultrafiltrate.

Metoclopramide is a potent antiemetic and gastric motility stimulator, structurally related to procainamide. It has been used before general anesthesia in labor to reduce the risk of maternal pulmonary aspiration of the stomach contents.[4] Diphenhydramine is an antihistaminic agent used in the treatment of allergies, nausea, and vomiting. It is also present in many nonprescription cough and cold remedies. Recent surveys indicate that about 10% to 20% of pregnant women take antihistamine-containing preparations at some point during pregnancy.[5] There is, however, limited information on the placental transfer of these drugs.[4, 6, 7]

In the course of pharmacokinetic studies of drug placental transfer in the chronically catheterized pregnant sheep we have collected and determined metoclopramide and diphenhydramine concentrations in maternal and fetal plasma and in amniotic and fetal lung fluids. In this report we describe a novel finding of marked accumulation of these drugs in fetal tracheal fluid in pregnant sheep.

Material and methods

Animal preparation. Studies were carried out on 11 pregnant sheep at 120 to 132 days' gestation. Surgery was performed with the animals under halothane anesthesia and silicone rubber catheters were implanted in a maternal femoral artery and vein and a fetal femoral artery, a lateral tarsal vein, the trachea,

Table I. Details of types and numbers of metoclopramide and diphenhydramine experiments

Experiment	*n*	*Ewe Nos.*
Maternal metoclopramide bolus injection of 40 mg	4	121, 127, 138, 140
Maternal metoclopramide infusion of 15 mg loading dose, then 0.21 mg/min for 90 min	4	60, 62, 98, 139
Fetal metoclopramide infusion of 5 mg loading dose, then 0.07 mg/min for 90 min	4	60, 62, 98, 139
Maternal diphenhydramine bolus injection of 100 mg	3	62, 98, 104

Fetal diphenhydramine infusion of 5 mg loading dose, then 0.17 mg/min for 90 min	4	121, 125, 133, 138

Table II. Mean ± SEM values for the ratio of drug concentration in tracheal fluid to that in fetal arterial plasma (TR/FA) and half-life values for drug in maternal and fetal arterial plasma and in tracheal fluid

Experiment	*TR/FA ratio*	*Maternal half-life (min)*	*Fetal half-life (min)*	*Tracheal fluid half-life (min)*
Maternal metoclopramide bolus	15.1 ± 0.7	87.5 ± 8.2	114.3 ± 15.7	127.9 ± 16.3
Maternal metoclopramide infusion	12.3 ± 1.7	55.6 ± 2.8	116.1 ± 17.1	94.5 ± 13.4
Fetal metoclopramide infusion	15.7 ± 1.7	83.5 ± 8.7	85.1 ± 20.7	81.8 ± 12.1
Maternal diphenhydramine bolus	2.8 ± 0.5	48.7 ± 3.6	47.3 ± 6.8	41.3 ± 1.8
Maternal diphenhydramine infusion	2.1 ± 0.4	51.3 ± 5.0	49.3 ± 11.0	38.5 ± 5.5
Fetal dephenhydramine infusion	4.2 ± 2.3	35.8 ± 5.5	53.8 ± 4.7	47.3 ± 5.3

and the amniotic cavity. The tracheal catheter (2.2 mm outside diameter) was inserted between adjacent tracheal rings, 1 cm below the larynx, with the catheter tip lying just above the carina. It did not impair the free flow of fluid out of the lung via the upper airway. After surgery, the ewes were placed in pens in the company of other sheep. On an experimental day, the sheep was transferred to a monitoring cart adjacent to the holding pen.

Experimental protocol. A total of 23 experiments were conducted on the 11 sheep. Details of the experiments are given in Table I. Experiments were performed from 3 to 14 days (mean = 7.2 ± 1.0) after surgery. The two drugs were administered intravenously to the ewe or fetus. In the case of infusions of metoclopramide and diphenhydramine, the paired maternal and fetal infusions to each animal were given 48 hours apart. In the other situations involving multiple experiments in the same animal, a minimum of 48 hours elapsed between separate experiments.

Infusions of drug were carried out with a Harvard infusion pump (Model 944, Harvard Apparatus, Millis, Massachusetts); the volume infusion rate was 0.017 ml/min. Metoclopramide hydrochloride (Reglan Injectable, 5 mg/ml, A. H. Robins Co., Montreal, Quebec, Canada) and diphenhydramine hydrochloride (Benadryl Injectable, 50 mg/ml, Parke-Davis, Scarborough, Ontario, Canada) were diluted in 0.9% saline solution to the appropriate concentration immediately before administration. For the infusion studies, samples were simultaneously withdrawn at −5, 5, 15, 30, 45, 60, 75, 90, 95, 100, 105, 110, 120, 135, 150, 180, 210, 240, 270, 300, 330, and 390 minutes from the maternal (2.5 ml) and fetal (1.5 ml) femoral arterial, amniotic (1.5 ml), and tracheal (1.5 ml) catheters. For bolus metoclopramide injections, the same catheters were sampled at −5, 1, 3, 6, 10, 15, 20, 30, 45, 60, 90, 120, 150, 180, 210, 240, 270, 300, 360, and 420 minutes. For the diphenhydramine bolus injections, only 5- and 10-minute samples were collected in the first 10 minutes; otherwise the sampling regimen was identical.

In each experiment, the volume of fetal blood collected was replaced by an equal volume of maternal blood at intervals during the study. Plasma, tracheal and amniotic samples were stored at −20° C until analysis.

Physiologic measurements. During the experimental period, fetal arterial, tracheal, and amniotic pressures were measured with strain-gauge manometers (Statham Model P23Db, Gould Inc., Oxnard, California). Fetal heart rate was measured from the arterial pulse pressure by means of a cardiotachometer (Model 9857, Sensormedics, Anaheim, California). Fetal P_{O_2}, P_{CO_2}, and pH were measured with Il Micro 13 blood gas analyzer (Instrumentation Laboratories, Lexington, Massachusetts). The fetal effects of metoclopramide have previously been reported in preliminary form.[7] The fetal cardiorespiratory and behavioral effects of diphenhydramine are currently under investigation.

Drug analysis. Drug measurement of metoclopramide and diphenhydramine was accomplished with the use of capillary gas-liquid chromatographic methods, in which electron-capture and nitrogen/phosphorus selective detection, respectively, were used.[6, 8]

Pharmacokinetic analysis. The experiments re-

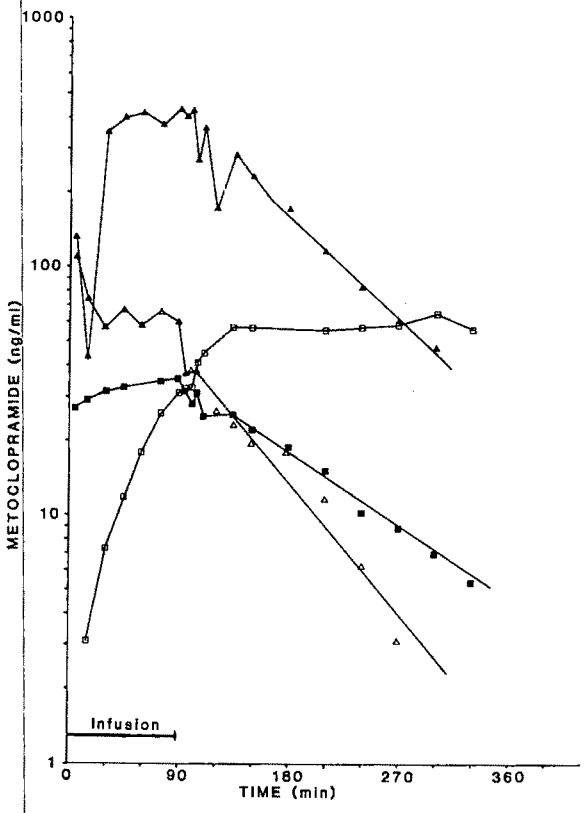

Fig. 1. Representative semilogarithmic plots of the maternal (△——△) and fetal (■——■) plasma, tracheal (▲——▲), and amniotic (□——□) metoclopramide concentrations versus time profiles in a pregnant ewe and fetus after a 15 mg intravenous bolus and an infusion of 0.21 mg/min for 90 minutes to the ewe.

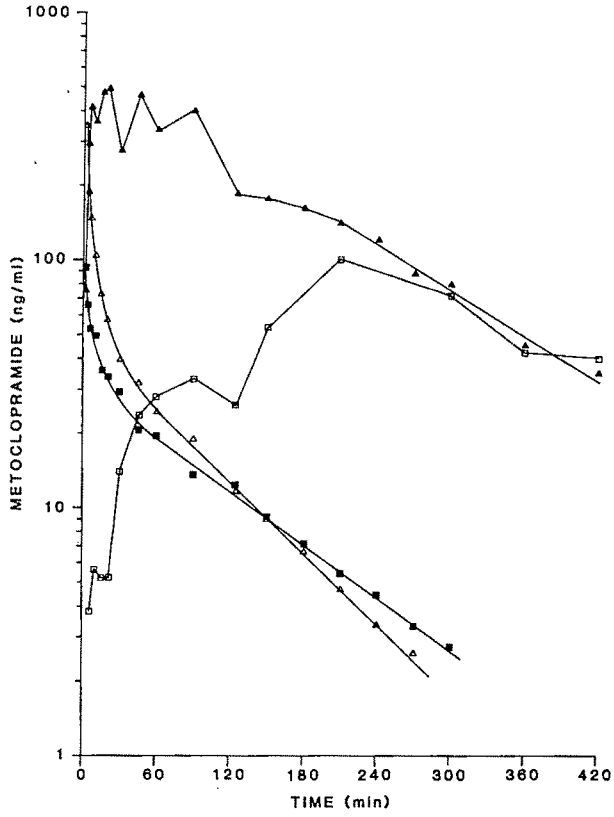

Fig. 2. Semilogarithmic plots of maternal (△——△) and fetal (■——■) plasma, tracheal (▲——▲), and amniotic (□——□) metoclopramide concentrations versus time profiles after a 40 mg maternal intravenous bolus.

ported in this paper were part of larger studies on the overall pharmacokinetics of metoclopramide and diphenhydramine in pregnant sheep. The pharmacokinetic parameters estimated from the plasma drug concentration versus time data from the bolus injection studies of the two drugs are presented in other reports.[7,8] In the present study, we calculated the maternal and fetal half-life for the drugs after bolus injection by linear regression analysis of the drug concentration versus time profile during the terminal elimination phase. The maternal volume of distribution (V_d) and elimination rate constant (β) data from these studies were also used to calculate the drug infusion rates (k_o) used in the steady-state infusion experiments by use of the equation:

$$C_{ss} = k_o/(V_d \times \beta)$$

where C_{ss} equals the desired maternal steady-state plasma concentration of the drug. The data from the infusion studies are being analyzed with use of a two-compartment open model of drug clearance in pregnancy proposed by Szeto[1] and will be the subject of further reports when the studies are completed. For the present article, we calculated maternal and fetal half-lives for the drugs in the infusion studies from linear regression analysis of the terminal elimination phase of the drug concentration versus time data after cessation of the infusion.

Results

Figs. 1 and 2 illustrate representative semilogarithmic concentration versus time profiles obtained for metoclopramide in each of the four fluid samples in experiments involving maternal infusion to a steady state (Fig. 1) and maternal intravenous bolus injection (Fig. 2). In both cases, the drug concentration in tracheal fluid was approximately tenfold to fifteenfold higher than in fetal plasma and a similar situation occurred with infusion of metoclopramide directly to the fetus (Table II). With the maternal metoclopramide infusions the levels in tracheal fluid reached their peak within 45 minutes of dosing, whereas with fetal infusion this occurred within 15 minutes. After cessation of the infusion, metoclopramide levels in tracheal fluid followed an exponential decline but with large periodic fluctuations for the first 1 to 2 hours (Figs. 1 and 2). However, throughout the entire time course of the experiment, the metoclopramide concentration in tra-

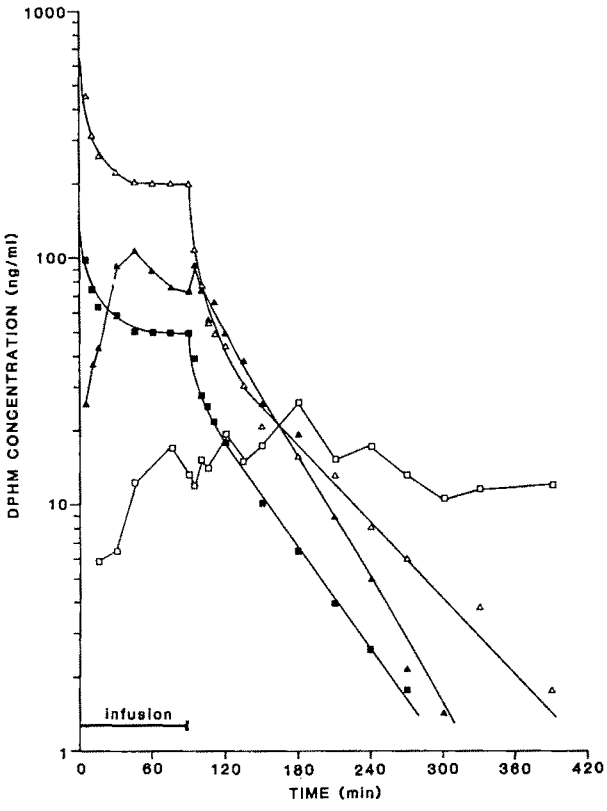

Fig. 3. Representative semilogarithmic plots of the maternal (△——△) and fetal (■——■) plasma, tracheal (▲——▲) and amniotic (□——□) diphenhydramine *(DPHM)* concentrations versus time profiles in a pregnant ewe and fetus after a 20 mg intravenous bolus and an infusion of 0.67 mg/min for 90 minutes to the ewe.

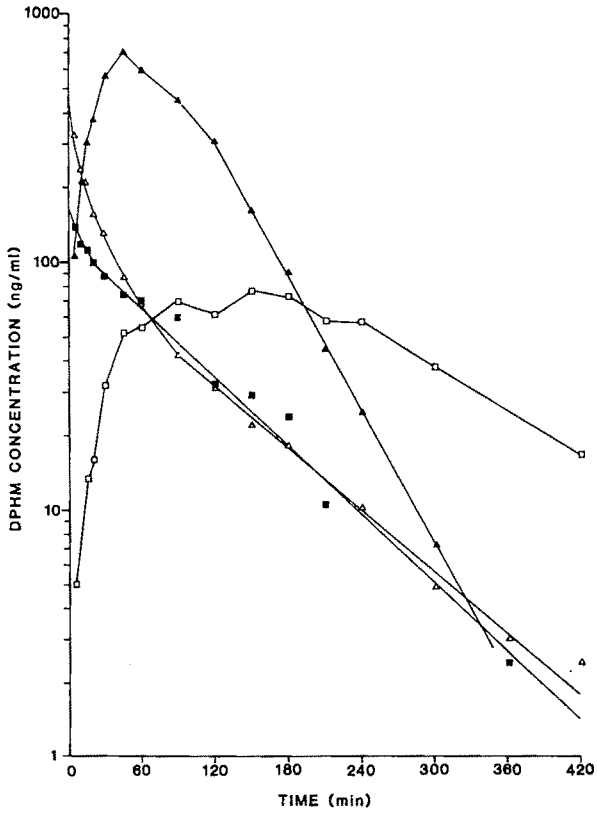

Fig. 4. Semilogarithmic plots of maternal (△——△) and fetal (■——■) plasma, tracheal (▲——▲) and amniotic (□——□) diphenhydramine *(DPHM)* concentrations versus time profiles after a 100 mg maternal intravenous bolus.

cheal fluid remained at least tenfold to fifteenfold higher than either the fetal or maternal plasma concentrations. On the other hand, the metoclopramide concentration in amniotic fluid rose progressively during the infusion period, reaching a plateau by 30 minutes after termination of the infusion (Fig. 1) and 210 minutes after bolus injection (Fig. 2). By 210 to 270 minutes, metoclopramide levels in the tracheal and amniotic fluid were similar. Also the highest concentration ultimately achieved in amniotic fluid was similar to the highest fetal plasma metoclopramide concentration observed in the initial phases of the experiments (mean ratio = 1.3 ± 0.2).

Figs. 3 and 4 show representative semilogarithmic plots of the concentration versus time profiles for diphenhydramine in each of the four fluid samples examined after maternal intravenous infusion to a steady state (Fig. 3) and maternal intravenous bolus injection of the drug (Fig. 4). As with metoclopramide, the levels of diphenhydramine in tracheal fluid were consistently higher than in fetal plasma. However, the extent of accumulation was less for diphenhydramine, with the tracheal fluid to fetal plasma ratio averaging 2 to 4 (Table II). A maximum ratio of ~5 was observed in the experiment illustrated in Fig. 4. The decline of the tracheal diphenhydramine concentration followed an exponential process; however, the marked fluctuations associated with metoclopramide excretion in tracheal fluid were not observed. Diphenhydramine in amniotic fluid reached plateau levels 45 to 90 minutes after drug administration and the amniotic diphenhydramine concentration exceeded those in fetal and maternal plasma and tracheal fluids by 70 to 200 minutes. However, the maximum level observed in amniotic fluid was substantially less than the highest diphenhydramine concentration in fetal plasma in each experiment (mean ratio = 0.3 ± 0.1).

The elimination of both drugs from maternal and fetal plasma was rapid (Table II). For metoclopramide, the average apparent terminal half-life in the fetus exceeded that in the ewe for all three types of experiments, and the overall average fetal value of 105.2 ± 10.3 minutes was significantly ($p < 0.05$, paired t test) higher than the mean maternal value of 75.5 ± 5.7 min. The apparent half-life of metoclopramide in tracheal fluid was very similar to that in fetal

plasma. For diphenhydramine, there were no consistent differences in half-life values in maternal and fetal plasma and tracheal fluid. After a bolus injection of metoclopramide and diphenhydramine, drug concentrations in amniotic fluid were declining by the end of the sampling period (Figs. 2 and 4). In contrast, with infusion to a steady state, metoclopramide concentrations in amniotic fluid were still at a plateau level at the end of the experiment (Fig. 1). This was sometimes the case for diphenhydramine (Fig. 3), but in most instances the amniotic fluid concentration of the drug was declining by the end of the experiment.

Comment

In adults, metabolism, excretion, and irreversible binding of many drugs, particularly amine compounds, by the lung are important processes in total body clearance of these agents, in part because the lung receives all of the cardiac output.[9] In the fetus, the percentage of combined ventricular output distributed to the lung is low (~6%), as is pulmonary blood flow (~28 ml/min · kg).[10] However, in spite of this, the results of the present study demonstrate marked accumulation of two amine drugs, metoclopramide and diphenhydramine, in fetal lung fluid. The overall average tracheal/fetal plasma concentration ratios for metoclopramide and diphenhydramine were 14.4 ± 1.0 and 3.0 ± 0.6, respectively. We do not yet have any data to explain this difference in the ratio, but the higher plasma protein binding in human adults reported for diphenhydramine (~80%),[11] as compared with metoclopramide (~20%),[12] may be involved. The cell types in the adult lung that are responsible for accumulation and metabolism have not been identified for all drugs, but pulmonary endothelial cells are known to be important in the uptake of a number of basic amine drugs.[13] We do not yet have any data to suggest specific mechanisms in the fetus. Also, we are not aware of any reports of accumulation of other drugs in fetal tracheal fluid. However, we have preliminary data indicating that the tracheal fluid/fetal arterial plasma concentration ratios for estradiol and progesterone are 0.40 and 0.22, respectively, suggesting no significant accumulation of these steroids in fetal tracheal fluid (Rurak DW, Leung PK, unpublished observations).

Even with the low rate of pulmonary blood flow in the fetus, the delivery of these drugs to the lung via the pulmonary circulation would appear to be more than sufficient to account for the levels observed in tracheal fluid. We base this argument on rough calculations done for an experiment involving maternal infusion of metoclopramide to a steady state. We have assumed a fetal weight of 2 kg, a lung fluid volume of 30 ml/kg,[2] a tracheal fluid excretion rate of 4 ml/hr · kg,[2] and a lung blood flow of 56 ml/min.[10] With these values and the measured metoclopramide concentrations in fetal plasma and tracheal fluid, it can be calculated that during the 90-minute infusion period approximately 13% of the metoclopramide delivered to the lungs would have to be taken up to account for the accumulation of the drug in tracheal fluid. However, it also appears that the rate of pulmonary uptake of metoclopramide would not be constant over the infusion period. Rather it would be greatest during the first ~5 minutes after the infusion is started, when extraction would have to be ~74%, and would thereafter decline progressively as the metoclopramide levels in tracheal fluid reached a plateau level. After cessation of the infusion, it would appear that further uptake of the drug by the lung would be very low. In essence, whatever the mechanism involved in metoclopramide accumulation in tracheal fluid, it appears to operate to create approximately a fifteenfold gradient in drug concentration between this fluid and fetal plasma. A large proportion of the total amount of metoclopramide taken up by the lung would be in the initial phase of drug administration to create the gradient. Once this is achieved, further uptake of metoclopramide is required only to replace that lost via tracheal fluid excretion from the airway. Of course, the above arguments apply equally well to diphenhydramine, with the difference being that the pulmonary extraction of this drug would have to be much less (~2% over the 90-minute infusion period) than for metoclopramide, given its much lower levels in tracheal fluid.

The accumulation of metoclopramide and diphenhydramine in fetal lung fluid could have several potential consequences. First, tracheal fluid could be a significant route of drug elimination from the fetus. For example, with metoclopramide, during the first 120 minutes after the start of the maternal infusion, approximately 3.2 μg of intact drug was excreted in tracheal fluid, assuming a rate of tracheal fluid production of 4 ml/hr · kg. This compares with a calculated total renal excretion for metoclopramide of 3.6 μg, assuming a glomerular filtration rate of 1 ml/min · kg[14] and no significant renal tubular resorption of metoclopramide. Although in vitro studies of the fetal liver have demonstrated the relatively early ontogenic appearance of oxidative, hydrolytic, and conjugative enzyme systems in man and other primates,[15] in vivo data from fetal lambs indicate a low hepatic extraction of propranolol.[16] Hence it may be that excretion of intact drug via lung fluid and urine is more important in overall fetal drug elimination. Second, since fetal lung fluid either enters the amniotic fluid compartment or is swallowed, a high drug concentration in tracheal fluid could contribute significantly to amniotic fluid levels. This could be particularly important in the case of metoclopramide (Figs. 1 and 2). Alternatively, fetal inges-

tion of tracheal fluid could be an important route for recycling of drug within the fetus. In this regard, the larger half-life of metoclopramide in fetal plasma compared with that in the ewe could be due, at least in part, to reuptake of the drug from the fetal lung into plasma. Finally, it would appear that at least some of the cellular elements within the lung could be exposed to very high drug concentrations. This would not be predicted by estimates of relative fetal drug exposure based on fetal/maternal plasma concentration ratios.[16] In summary, this potential route of drug excretion in the fetus deserves further investigation.

We thank A. H. Robins Canada Inc. (Montreal, Quebec, Canada) for the supply of metoclopramide.

Corrections

In the article by Edelstone et al., entitled "Effects of maternal anemia on cardiac output, systemic oxygen consumption, and regional blood flow in pregnant sheep" (AM J OBSTET GYNECOL 1987;156:740-8), the fourth sentence of the first paragraph of the Methods section should have been: "Local anesthesia (Xylocaine, 2%) was used for these catheter insertions."

In the article by Hustin and Schaaps, entitled "*Echocardiographic* and anatomic studies of the maternotrophoblastic border during the first trimester of pregnancy" (AM J OBSTET GYNECOL 1987;157:162-8), the title should have been "*Echographic* and anatomic studies of the maternotrophoblastic border during the first trimester of pregnancy."

Plasma atrial natriuretic peptide response to volume expansion in the ovine fetus

Michael G. Ross, M.D.,* M. Gore Ervin, Ph.D., Robert W. Lam, B.S., Lony Castro, M.D., Rosemary D. Leake, M.D., and Delbert A. Fisher, M.D.

Torrance, California

Atrial natriuretic peptide is a potent diuretic and vasorelaxant peptide secreted from the cardiac atria of adult mammals in response to increased intravascular volume. In sheep, fetal plasma levels of atrial natriuretic peptide are significantly greater than maternal levels, but the factors that control fetal release of atrial natriuretic peptide have not been defined. The present studies were conducted to determine whether the fetus responds to increased intravascular volume by atrial natriuretic peptide secretion. The mean (± standard error of the mean) atrial natriuretic peptide of basal fetal plasma (115 ± 24 pg/ml) in chronically catheterized ovine fetuses (131 ± 1 days' gestation) was significantly greater than atrial natriuretic peptide levels of basal maternal plasma (56 ± 12 pg/ml). In response to successive 30-minute intravenous infusions of 0.9% saline solution at 0.5 and 1.0 ml/kg/min, fetal plasma atrial natriuretic peptide significantly increased to a maximum of 409 ± 72 pg/ml during the high-dose saline infusion and returned to 234 ± 83 pg/ml during a 30-minute recovery period. The increase in fetal plasma atrial natriuretic peptide was significantly correlated with the volume of saline solution infused ($r = 0.68$). During the saline infusion, a significant increase in fetal blood volume and heart rate was noted. Fetal blood pressure, maternal plasma levels of atrial natriuretic peptide, and fetal and maternal plasma osmolality remained unchanged. Despite elevated basal levels of plasma atrial natriuretic peptide, the third-trimester ovine fetus responds to increases in intravascular volume with a further increase in atrial natriuretic peptide secretion. (Am J Obstet Gynecol 1987;157:1292-7.)

Key words: Blood volume, atrial natriuretic peptide, cardiac

Atrial natriuretic peptide comprises a group of biologically active peptides synthesized by mammalian atrial cardiocytes. Histochemical studies suggest that specific atrial granules store and release the polypeptide, which is consistent with a secretory function for the atrial cardiocyte. Atrial natriuretic peptide has been demonstrated to produce a significant natriuresis and diuresis in mammals, principally via an increase in glomerular filtration; a tubular effect of atrial natriuretic peptide is controversial. Atrial natriuretic peptide also has significant effects on systemic blood pressure and renin, aldosterone, and arginine vasopressin secretion. In adult mammals, increased secretion of atrial natriuretic peptide occurs in response to intravascular volume expansion, with atrial stretch believed to be the actual stimulus.[1,2]

Although the secretion, function, and metabolism of atrial natriuretic peptide have been studied in a variety of species of adult mammals, little is known of the secretion of atrial natriuretic peptide in the fetal mammal. The present studies sought to determine if the chronically catheterized ovine fetus responds to an intravascular volume load with increased secretion of atrial natriuretic peptide.

Methods

Animals and surgery. Five studies were performed in four mixed-breed Western cross-bred ewes with singleton fetuses ranging in age from 127 to 134 days (mean gestational age, 131 ± 1 day). Animals were housed indoors in individual steel study cages and maintained under a controlled lighting regimen of 12 hours of light and 12 hours of darkness. Both food (alfalfa pellets) and water were available ad libitum, except for the withholding of food during the 24-hour period immediately before surgery.

Anesthesia for surgery was induced by an intramuscular injection of ketamine hydrochloride (20 mg/kg) plus atropine sulfate (30 μg/kg) and subsequently maintained by a continuous intravenous infusion of ketamine (15 mg/hr · kg^{-1}). Lidocaine (Xylocaine) (1%) was

applied locally before all incisions. The uterus was exposed by a midline abdominal incision, and a small hysterotomy was performed to provide access to a single fetal hindlimb. Tygon catheters (1 mm inner diameter; 1.8 mm outer diameter) were placed in the fetal dorsal hindlimb vein and artery and threaded to the inferior vena cava and abdominal aorta, respectively. Before hysterotomy closure, a plastic catheter (Corometrics Medical Systems, Wallingford, Conn.) was sutured to the distal tip of the fetal hindlimb to provide access to the amniotic cavity. The uterus, maternal fascia, and skin were closed in separate layers with sutures. The maternal femoral artery and vein in one leg were catheterized, and the catheters were threaded to the aorta and inferior vena cava, respectively. All catheters were exteriorized to the maternal flank and placed in a cloth pouch sewn to the ewe's flank.

Fetal vascular catheters were maintained patent by filling the catheter deadspace (1 ml) with 1000 U/ml sodium heparin and sealing with sterile plastic caps. Maternal vascular catheters were filled with heparinized saline solution (10 μU/ml), and both fetal and maternal catheters were flushed daily. Immediately after surgery and twice daily for the succeeding 5 days, fetuses received an intravenous infusion of oxacillin (30 mg/kg) and gentamicin (4 mg/kg). Oxacillin (400 mg) and chloramphenicol (1 gm) were also administered into the maternal vein and amniotic cavity.

Experimental protocol. All experiments were performed on unanesthetized ewes standing in the same individual cages in which they were maintained. Fetal arterial blood pH values were assessed, and studies were undertaken only if the fetal arterial pH was greater than 7.3. Before an initial 60-minute basal period, 2 ml of fetal blood was withdrawn, labeled with chromium 51 (ICN Radiochemicals, Irvine, Calif.), and reinjected into the fetal vein as described by Brace.[3] After equilibration for 45 minutes, fetal and maternal blood samples were collected at 30 and 15 minutes before initiation of saline infusion. At time 0, a fetal intravenous infusion of 0.9% saline solution (0.5 ml/kg/min) was initiated and maintained for 30 minutes. At time +30, the saline infusion was increased to (1.0 ml/kg/min) for an additional 30 minutes. At +60 minutes, the saline infusion was discontinued, and the fetus was observed for a 30-minute recovery period. Infusion rates were based on estimated fetal body weights from the formula: fetal body weight (kg) = (0.096 × gestational age [days]) − 9.2228, as described by Robillard and Weitzman.[4]

Fetal arterial blood samples (2.5 ml) were collected at 10-minute intervals after initiation of the saline infusion. Blood samples were placed into iced tubes containing Trasylol (250 kallikrein units/ml blood), trypsin inhibitor (40 μU/ml), and K_2 ethylenediaminetetraace-

tic acid (1 mg/ml). Chromium 51 activity was determined in a 300 μl aliquot of each sample. Hematocrit determinations were performed in triplicate on each blood sample. All samples were centrifuged immediately. Osmolality was measured in aliquots of the prepared plasma; residual plasma was stored at −20° C until assayed for atrial natriuretic peptide. In addition, 0.5 ml of blood was collected into heparinized tuberculin syringes for immediate measurements of pH, P_{O_2}, and P_{CO_2}. The total volume of fetal blood withdrawn at each sample (3.0 ml) was replaced with an equal volume of heparinized maternal blood withdrawn before the study. Fetal arterial blood pressure and amniotic cavity pressures were monitored continuously by means of a Beckman R-612 physiologic recorder (Beckman, Palo Alto, Calif.) with Statham P23 transducers. Fetal blood pressure was corrected for amniotic fluid pressures, and fetal heart rate was computed from the arterial pulse. Repeat samples of maternal arterial blood were drawn at 20 and 30 minutes of the 1.0 ml/kg/min infusion.

Analytic methods. Plasma determinations of atrial natriuretic peptide were performed by a recently described[5] radioimmunoassay method developed in our laboratory that uses synthetic human atrial natriuretic peptide (1 to 28) obtained from Bachem, Inc. (Torrance, Calif.). Briefly, atrial natriuretic peptide was coupled with bovine thyroglobulin by means of carbodiimide, and the coupled material was used to generate antisera in New Zealand white rabbits. Radiolabeled atrial natriuretic peptide was prepared with Iodogen (Pierce Chemical Co, Rockford, Ill.). Plasma samples were acidified with 100 μl of 1N hydrochloric acid and extracted on C18 Sep-Pac columns (Waters Associates, Milford, Mass.). Columns were washed with 10 ml methanol followed by 10 ml triethylamine acetate buffer (pH 4.0). Acidified plasma samples (1 ml) were added slowly to Sep-Pac columns, and the columns were washed with 10 ml triethylamine acetate buffer (pH 4.0). The absorbed peptide was eluted with 4.0 ml of 80% methanol in triethylamine acetate buffer, and the eluates were dried in a Speed-Vac concentrator (Savant Instruments, Hicksville, New York). Dried fractions were stored frozen (−20° C) until dissolved in radioimmunoassay buffer immediately before assay.

The entire atrial natriuretic peptide-radioimmunoassay procedure was performed at 4° C. The assay buffer was 0.01 mol/L phosphate-buffered saline solution containing 0.1% bovine serum albumin and 0.1% triton X-100, with a pH of 7.4. Duplicate 50 or 100 μl plasma extracts or standards were mixed with 100 μl of antiserum in a total volume of 300 μl and incubated overnight at 4° C. Then 100 μl of iodinated tracer (~5000 cpm) was added, mixed, and incubated overnight at 4° C. Bound and free fractions were separated by adding goat antirabbit γ-globulin (50 μl of 1:10 dilution) and normal rabbit serum (50 μl of 1:50 dilution). Polyethylene glycol 6000 (75 μl of 25% solution) was added, and the tubes were centrifuged (2000 rpm at 4° C) for 30 minutes. The supernatant was aspirated, and the radioactivity in the precipitates was measured in a γ-counter.

A typical standard curve ranged from 1 to 500 pg/tube, which was plotted as B/Bo versus picograms per tube. The sensitivity of the assay, which was defined as the least amount of atrial natriuretic peptide distinguishable from 0 at the 95% confidence limit, was 2 pg/tube. Cross reactivities of our antiserum with a variety of atrial natriuretic peptide analogs were human atrial natriuretic peptide (one to 28 amino acids) 100%, rat atrial natriuretic peptide (one to 28 amino acids) 43%, rat atriopeptin I (five to 25 amino acids) 1%, rat atriopeptin II (five to 27 amino acids) 0.2%, rat atriopeptin III (five to 28 amino acids) 0.1%, and rat atriopeptide (13 to 28 amino acids) <0.1%.

The mean recoveries of synthetic human atrial natriuretic peptide added to pools of either ovine adult plasma (n = 10) or fetal plasma (n = 10) were similar

Saline (1.0 ml/kg/min) (min)			*Recovery (min)*		
40	*50*	*60*	*70*	*80*	*90*
		7.36 ± 0.01			7.37 ± 0.01

35.1 ± 1.4*	35.1 ± 1.3*	35.3 ± 1.5*	35.7 ± 1.4*	35.7 ± 1.5*	35.2 ± 1.5*
		295 ± 2			297 ± 2

(81% ± 6% and 85% ± 5%, respectively). Recovery of iodine 125–labeled atrial natriuretic peptide also was similar (78% ± 3%). The intra-assay and interassay coefficients of variation were 11% and 13%, respectively. All values of ovine atrial natriuretic peptide concentrations represent immunoreactive human atrial natriuretic peptide.

Blood pH, P_{O_2}, and P_{CO_2} values were determined at 39° C with a Radiometer BM 33 MK2-PHM 72 MK2 acid-base analyzer system (Radiometer Co., Copenhagen, Denmark). Plasma and urine osmolalities were measured by freezing-point depression on an Advanced-Digimatic osmometer (Model MO, Advanced Instruments, Inc., Needham Heights, Mass.). Chromium 51 activity was determined on a 1282 Compugamma γ-counter (LKB Wallac, Turku, Finland). Blood volume was determined as described by Brace[3]; corrections were made for the removal of chromium 51 activity caused by fetal blood sampling.

Statistics. All values are expressed as the mean ± standard error of the mean. Differences over time were assessed by one-way analysis of variance for repeated measures. Whenever a significant F test of $p < 0.05$ was observed, comparisons of the control means to each of the other group means were performed by the Dunnett test ($p < 0.05$). Maternal basal and infusion plasma levels were compared by paired *t* test.

Results

Maternal. Maternal arterial blood pH, P_{O_2}, P_{CO_2}, and hematocrit values, as well as plasma osmolality and atrial natriuretic peptide concentrations, are summarized in Table I. None of the maternal parameters changed significantly during the saline infusion to the fetus.

Fetal. There was no change from mean basal values of fetal arterial pH (7.37 ± 0.09), P_{O_2} (22 ± 2 mm Hg), systolic (57 ± 3 mm Hg), diastolic (35 ± 1 mm Hg), or mean (43 ± 1 mm Hg) blood pressure, or plasma osmolality (296 ± 2 mosm) during the saline infusions to the fetus (Table II). There was a small but significant decrease in fetal P_{CO_2} during the recovery period. Fetal heart rate tended to increase during the saline infusion, although a statistically significant increase was not noted until the recovery period. Mean fetal hematocrit level decreased significantly from a basal value of 37.0% ± 1.8% to 35.1% ± 1.3% during the saline infusion period (Table II).

As shown in Fig. 1, *A*, fetal blood volume increased significantly from a basal value of 359 ± 16 to a peak value of 434 ± 46 ml during the high-dose saline infusion. Basal levels of fetal plasma atrial natriuretic peptide (115 ± 24 pg/ml) were significantly greater than were basal maternal levels. As shown in Fig. 1, *B*, fetal plasma atrial natriuretic peptide significantly increased to a maximum of 409 ± 72 pg/ml during the saline infusion and returned to basal levels during the recovery period. The increase in fetal plasma atrial natriuretic peptide was significantly correlated with the volume of saline infused by a second-order polynomial relation ($r = 0.68$; $p < 0.001$; Fig. 2):

$$y = -5.83\,x^2 + 85.12\,x + 81.65$$

Comment

In the present study, basal levels of plasma atrial natriuretic peptide were significantly higher in the fetus than in the maternal ewe. This could be explained by a relative increase in the rate of fetal atrial natriuretic peptide secretion or a decrease in the rate of fetal metabolism of atrial natriuretic peptide when compared with the ewe. We[6] previously demonstrated an extremely rapid plasma clearance of atrial natriuretic peptide in the ovine fetus (94 ± 7 ml/min/kg), which suggests that the metabolic clearance of atrial natriuretic peptide is not reduced in the fetus. Direct information regarding the fetal production of atrial natriuretic peptide is not yet available. Fetal cardiac output and right heart function are proportionately

increased when compared with the adult, potentially stimulating atrial natriuretic peptide secretion via an increase in fetal atrial distention. In rats[7] a regulatory and permissive role for glucocorticoids and mineralocorticoids in the release of atrial natriuretic peptide has also been demonstrated. The unique fetal steroid endocrine milieu associated with increased plasma concentrations of deoxycorticosterone, progesterone, and aldosterone may potentiate fetal atrial natriuretic peptide secretion.

Despite basal fetal plasma levels of atrial natriuretic peptide twofold greater than maternal levels, the fetus responded to saline infusion with a further increment in plasma concentration. Thus despite what is likely a basal hypersecretion of atrial natriuretic peptide, the fetus retains significant atrial natriuretic peptide secretory reserves. The plasma atrial natriuretic peptide response to volume loading is consistent with the response to volume loading reported in adult mammals.[9] Whether the increase in plasma atrial natriuretic peptide has significant renal effects in the fetus is unknown at present. However, in a study of the effects of intravascular saline infusion (50 ml over 30 minutes) to the ovine fetus, Hurley et al.[8] demonstrated a significant increase in the fetal glomerular filtration rate and a decrease in fractional sodium resorption. These findings are consistent with reported renal actions of atrial natriuretic peptide, including a diuresis and natriuresis associated with increased glomerular filtration.

In the present experiments, a significant decrease occurred in the fetal hematocrit level in response to the successive intravenous saline infusions (Table II). This was not caused by fetal blood sampling, since each fetal sample was replaced euvolemically with maternal blood. Rather, the decrease in hematocrit level resulted from fetal plasma volume expansion after intravascular saline solution. Consequently, fetal blood volume, as calculated by chromium 51–labeled red cell dilution, increased progressively during the infusion. Presumably, the blood volume expansion and subsequent atrial stretch stimulate an increase in atrial natriuretic peptide secretion.

A significant increase in fetal heart rate was noted during the saline infusions to the fetus. Fetal systolic, diastolic, and mean blood pressure did not change significantly during the infusions despite the increase in plasma concentration of atrial natriuretic peptide. Although a hypotensive response to atrial natriuretic peptide infusion has been noted in in vitro preparations, this has not been a consistent observation in vivo.[9] A marked hypotensive action of atrial natriuretic peptide has been demonstrated in models of increased renin/angiotensin, apparently as a result of atrial natriuretic peptide antagonism of angiotensin-induced vasoconstriction.[9] Although the ovine fetus demonstrates increased plasma renin activity,[10] plasma angiotensin II levels are comparable with values in adult ewes.[11] The role of basal levels of angiotensin in blood pressure homeostasis and thus the susceptibility to vasodilating effects of atrial natriuretic peptide appear to be minimal in the ovine fetus.[12]

In the conscious adult sheep preparation, hypotensive effects of atrial natriuretic peptide apparently result from a decrease in cardiac output.[13] Relaxation of venous smooth muscle with a reduction in venous return and stroke volume results in a reflex increase in peripheral resistance and an increase in heart rate. The increase in heart rate noted in the present study is consistent with these actions. A hypotensive effect might have been mitigated by fetal reflex arterial constriction and the saline-induced blood volume expansion.

Fetal basal plasma osmolality and intravascular water are dependent on maternal levels; changes in maternal hydration induce transplacental water flows that acutely alter fetal homeostasis. We previously demonstrated that in response to maternal plasma hyperosmolality and the resultant fetal blood volume contraction, there is an increase in fetal arginine vasopressin secretion that decreases fetal urine and lung fluid flows.[14, 15] The fetus preserves body water at the expense of amniotic fluid production.[16] It is probable that a counterregulatory endocrine system, such as atrial natriuretic peptide, exists to adjust to acute fetal blood volume expansion. Whether fetal atrial natriuretic peptide modulates in utero urine production and lung fluid secretion remains to be determined.

We are grateful to Jim Humme and Glenda Calvario for their technical assistance.

Effect of chronically elevated androgen or estrogen on the glucose tolerance test and insulin response in female rhesus monkeys

Reinhart B. Billiar, Ph.D., Donald Richardson, M.D., Robert Schwartz, M.D., Barry Posner, M.D., and Brian Little, M.D.

Montreal, Quebec, Canada, Pittsburgh, Pennsylvania, and Providence, Rhode Island

Insulin concentrations, in response to an intravenous glucose bolus after a 24-hour fast, have been studied in female rhesus monkeys in which the circulating levels of androstenedione and testosterone or estrone and estradiol have been increased for as long as 4½ years. No significant differences were observed in the basal insulin or C-peptide concentrations in the androgen or estrogen-treated animals compared with each other or with normal cycling, nontreated control animals. The insulin and C-peptide responses to intravenous glucose were similar in control and androgen-treated monkeys. Compared with both the control and androgen-treated monkeys, the responses of the estrogen-treated monkeys tended to be lower but were not significantly different. The glucose disappearance rate after the intravenous glucose bolus was not significantly different in androgen and control monkeys but was significantly slower during the initial 30 minutes in the estrogen-treated monkeys compared with both the control and androgen-treated monkeys. These studies suggest that chronically elevated androgen levels in the mature female subhuman primate do not lead to insulin resistance or overt glucose intolerance. (Am J Obstet Gynecol 1987;157:1297-302.)

Key words: Androgens, insulin resistance, primates

Increased circulating androgen concentration in the adult human female has been associated with hyperinsulinemia and insulin resistance as measured by fasting basal insulin levels and the insulin response to an oral or intravenous glucose tolerance test.[1-5] Treatment of women with polycystic ovarian disease with spironolactone lowered both their elevated serum testosterone and basal immunoreactive insulin concentrations, which suggested that androgens may be one factor in the development of insulin resistance.[6] Analysis of factors such as weight and androgen concentrations relative to insulin resistance also supported the role of increased androgen production as a factor in the development of insulin resistance in women.[3] However, hyperandrogenism is often associated with hyperinsulinism caused by genetic disorders of insulin action,

Female rhesus monkeys were implanted subcutaneously with silicone rubber tubing that was 4 cm long and packed with estrone or androstenedione or empty (controls). The control and estrone animals and two of the androstenedione animals were started in May 1982, while the remaining four androstenedione-treated animals were first implanted with steroid in July 1980. The tubing with steroid was replaced every 6 to 8 months. Food was withheld for 24 hours before blood samples were obtained during ketamine anesthesia. Two basal samples were obtained 10 to 15 minutes apart and the average of the two values used for calculation of basal concentrations.
*Mean ± SEM.

and therefore it has been suggested that hyperandrogenism in some women might result in part from an action of insulin on the ovarian responsiveness to luteinizing hormone.[7]

One approach to study the role of androgens in insulin resistance in women is to decrease the excessive androgen production[6] or administer antiandrogens[8] and follow the insulin resistance. Studies in obese women with polycystic ovarian disease treated with hypocaloric diets with or without antiandrogenic therapy do not support a major role for androgen in the development of insulin resistance.[8] The interpretation of the results of that study is complicated by the weight loss in combination with the antiandrogen treatment since associated obesity is known to be a major factor in insulin resistance in women with polycystic ovarian disease.[3] Ethinyl estradiol was also administered with the antiandrogen cyproterone acetate. The combination of these two factors, weight loss and estrogen, might mask the role of androgens in insulin resistance in women with polycystic ovarian disease.

An alternative approach is to establish a hyperandrogen condition in the absence of obesity and measure basal insulin levels and the insulin response to a glucose bolus. The present study reports the results of the comparison of basal insulin levels and subsequent insulin response to a bolus of glucose in female monkeys that have elevated circulating androstenedione and testosterone, produced by silicone rubber implants packed with crystalline androstenedione for 2 to 4½ years. The results are compared with those of female monkeys with chronic exposure to elevated estrone and estradiol levels. These monkeys are part of an ongoing investigation to study the effect of chronically elevated gonadal steroids on the endocrinology and physiology of female primates.[9]

Material and methods

Adult female rhesus monkeys with regular menstrual cycles were caged individually in a room at a controlled temperature of 22° C and with 12-hour light to 12-hour dark cycles. The hormonal treatment and weight of

these animals have been previously reported.[9] For the present study, three additional nonobese female monkeys from the colony with regular menstrual cycles were added to the control group. At the time of the January 1985 test, the weight of the animals were: controls, 4.9, 5.1, 5.5, 5.6, 5.6, 6.0, and 6.0 kg; androstenedione-treated, 5.0, 5.4, 5.4, 6.7, and 7.6 kg; and estrogen-treated, 3.3, 5.1, 5.7, and 6.4 kg. The animals received Ralston-Purina high-protein chow diet 5045 once daily and water ad libitum and were given fresh fruit twice weekly. All food and wood shavings were removed approximately 24 hours before blood samples were taken for basal values and an intravenous glucose bolus was given. Monkeys used in these studies were maintained in accordance with the guidelines of the Committee on Animals of the University of Pittsburgh School of Medicine and those prepared by the Committee on Care and Use of Laboratory Animals of the Institute of Laboratory Animal Resources (1978 Department of Health, Education and Welfare publication National Institutes of Health 78-23, National Research Council).

Serum androstenedione concentrations were determined by a modification of the radioimmunoassay (RIA) method previously described[9] with methylene dichloride substituted for ether for extraction of the serum samples, and Celite column chromatography replaced paper chromatography for the purification. The androstenedione antiserum was purchased from Hazelton Laboratories American (Vienna, Va.). Serum testosterone and estradiol concentrations were determined by the same assays as reported.[9]

Plasma glucose concentrations were determined by the glucose oxidase method, insulin by the human double antibody RIA method,[10] and C-peptide by a single antibody RIA method for human C-peptide (Serono RIA kit, Serono Diagnostics, Inc., Braintree, Mass.). In the insulin assay the mean difference of samples assayed in duplicate in the same assay was 2.5%. The mean difference of 19 samples assayed in two separate assays was 7.4% ± 6.5% (SD).

After 24 hours of fasting, the monkeys were anesthetized with ketamine, and a catheter was inserted into the antecubital or femoral vein for the withdrawal of blood samples or the administration of a bolus of glucose in saline solution (0.5 gm/kg body weight). After two blood samples were obtained 10 to 15 minutes apart for the determination of basal glucose, insulin, and C-peptide concentrations, the glucose was given as a bolus over 30 seconds, followed by a flush of saline solution. After completion of the glucose injection, 3 ml blood samples were then taken in heparinized syringes at 2, 5, 10, 20, 30, 40, and 50 minutes in the January 1985 study and an additional 60-minute sample in the April 1984 study. The blood was centrifuged at 4° C, and the plasma was stored at −60° C for glucose, insulin, and C-peptide analyses. Statistical analyses were by one-way analysis of variance and *t* test for multiple comparison.[11] The data of the April 1984 and January 1985 studies were analyzed separately and not pooled together. The variance between the standard deviations of each analysis between groups was tested by the Barlett test.[11]

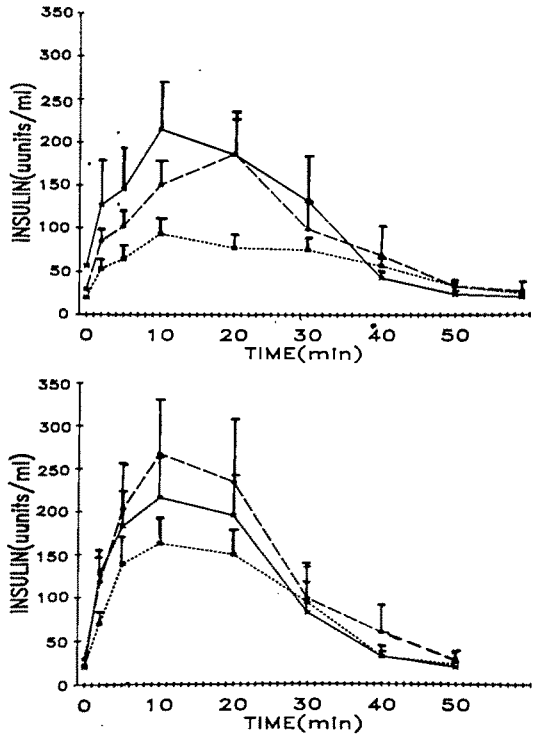

Fig. 1. Insulin responses to an intravenous bolus of glucose in fasted control, androstenedione-, or estrone-treated female rhesus monkeys. After a 24-hour fast and blood samples were obtained for basal plasma concentrations, each monkey was given an intravenous bolus of glucose in saline solution (0.5 gm/kg body weight), and blood samples were collected at time periods indicated. Hormonal treatment was as described in the legend of Table I. The number of animals studied in each group in April 1984 and January 1985 is listed in Table II. *Top panel,* results of the test done in April 1984. *Bottom panel,* January 1985 (see Methods section). (X——X = Controls; o - - - - o = androstenedione-treated; □ · · · · □ = estrone-treated.)

Results

Serum concentrations of testosterone, androstenedione, and estradiol in the monkeys during the early follicular phase or periods of anovulation were in the same range as previously reported[9] (Table I). Although not measured at the time of the insulin studies, previous studies indicated that the estrone capsules results in serum concentrations of estrone of approximately 150 pg/ml compared with estrone concentrations of 65 pg/ml in the control or androstenedione-treated monkeys.[9]

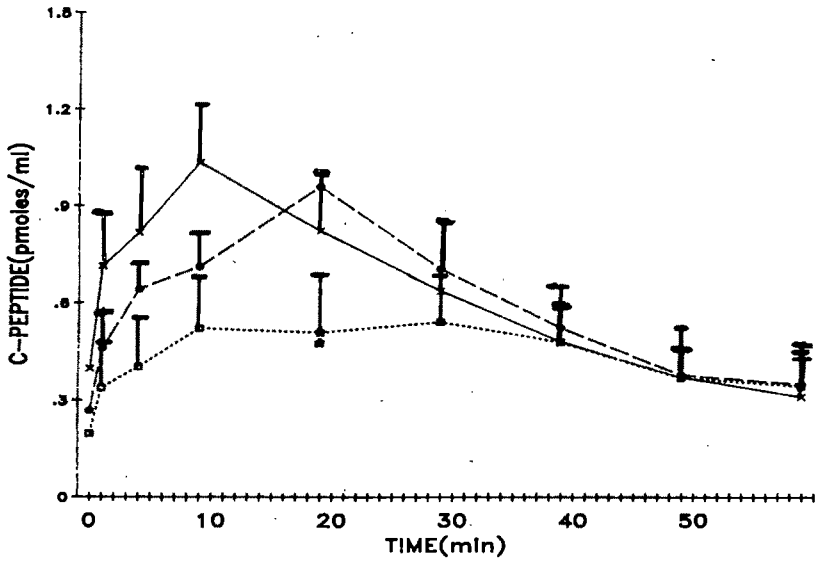

Fig. 2. C-peptide response to an intravenous bolus of glucose in fasted control, androstenedione-, or estrone-treated female rhesus monkeys. The study is that described in the legend of Fig. 1 and Tables II and III (April 1984). The number of animals studied is listed in Table II. (*$p < 0.01$ compared with maximal response of control [X——X] or androstenedione [o - - - - o] animals.)

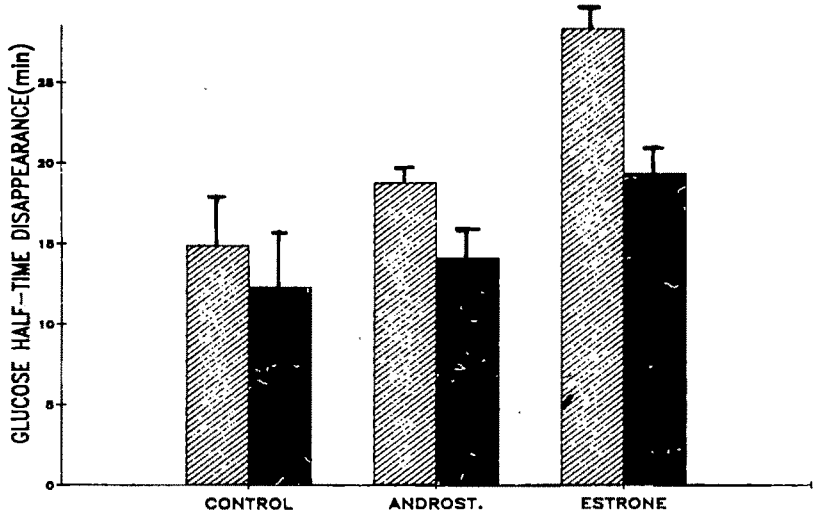

Fig. 3. The half-time (t-½) disappearance rate of glucose after an intravenous glucose bolus to fasted control, androstenedione-, and estrone-treated female rhesus monkeys. The study is described in the legends of Fig. 1 and Tables II and III. The number of animals studied in each group in April 1984 and January 1985 is listed in Table II. Plasma glucose concentrations were converted to their ln concentrations, and t-½ was calculated from least squares analysis of the disappearance rates. (▨ = Study done in April 1984; ■ = repeat study done in January 1985.)

Chronic and continuous elevation of circulating levels of androgens or estrogens did not significantly increase the basal concentrations of plasma glucose, insulin, or C-peptide after a 24-hour fast (Table II). Although the basal levels of insulin tended to be highest in the androgen-treated female monkeys compared with control (January 1985) and the estrogen-treated monkeys, they were not significantly different and returned to similar basal concentrations in all three groups 50 minutes after the administration of an intravenous bolus of glucose (Fig. 1). One of the four control animals had an unexplained high basal concentration of insulin in April 1984 that was not repeated in January 1985, at which time it was in the normal range (Table II).

The insulin-response to an intravenous bolus injec-

*After basal plasma samples were obtained, the monkeys were given an intravenous bolus of 0.5 gm glucose/kg body weight over 30 seconds and blood samples were collected at 2, 5, 10, 20, 30, 40, and 50 minutes in the January 1985 study and an additional sample at 60 minutes in the April 1984 study. Basal values were subtracted from the concentrations obtained between 2 and 30 minutes, the values were plotted on graph paper, and the area under the curves was integrated by a "smart pad" and software program Lotus 1, 2, and 3.

†The ratio of maximal insulin/C-peptide concentrations was obtained from the data of Figs. 2 and 3.

‡$p < 0.05$ compared with control and androstenedione-treated animals.

tion of glucose was tested in the control, androgen-, and estrogen-treated female monkeys (Figs. 1 and 2, and Table III). The maximal glucose response and cumulative plasma glucose concentration were not different in all three groups in both test periods. However, the glucose disappearance rate (i.e., t-½, Fig. 3) was significantly slower for the time interval of 2 to 30 minutes in the estrogen-treated monkeys in both test periods. (Plasma glucose concentrations returned to basal levels at 30 or 40 minutes after injection.) Although the insulin response to the glucose bolus was not statistically different among the three groups, the insulin response tended to be less in the estrone-treated female monkeys in both test periods (Fig. 1). The plasma concentrations of insulin and C-peptide in response to the intravenous glucose bolus were similar among the three groups (Table III), as were the calculated mean ratios of the total insulin/C-peptide responses: 252, 219, and 205. Although the insulin responses were not different among the three groups, the response differed in that the variance in the plasma insulin concentrations of the estrone-treated monkeys was significantly less than that of the control or androstenedione-treated monkeys. Thus the estrone-treated animals had a more uniform insulin response to the intravenous glucose bolus than either the control or androgen-treated animals. Because of the difference in the variance of the estrone group compared with the control and androstenedione-treated animals, the insulin response (Table III) was also analyzed by the Kruskal-Wallis test. There was no significant difference between groups in either the April 1984 ($p = 0.05$ to 0.1) or January 1985 ($p > 0.1$) insulin response.

The insulin/glucose (area) ratios of the estrogen-treated animals were significantly less in one test (April 1984) compared with either control or androgen-treated animals and tended to be lower in the second test (January 1985) but was not significantly different.

Comment

During the past several years, considerable attention has been focused on the associated increase of androgen production in women and the development of insulin resistance.[1-8] It is unclear whether increased androgen production can lead to insulin resistance, whether increased circulating insulin enhances luteinizing hormone stimulation of ovarian androgen secretion,[7, 8] or whether the two phenomena are associated with an additional, unknown metabolic parameter(s). The present studies examined the question of the effect of increased circulating androgens on basal insulin concentrations and the insulin response to intravenous glucose in a primate model where the androgen concentrations have been chronically elevated by means of an androstenedione silicone rubber implant. Androstenedione and testosterone serum concentrations were three to four times higher than that present in control or estrone-treated female monkeys (Table I). Since it has been reported that the intravenous glucose tolerance test in monkeys is variable,[12] the glucose tolerance test was repeated twice in the same animals at an interval of 10 months. The intravenous glucose-tolerance curve and insulin response of the control andandrogen-treated monkeys were similar to those reported for a larger number of normal rhesus monkeys.[13] The results indicate that a chronic elevation of the circulating concentrations of androstenedione and testosterone for 2 to 4½ years does not alter either the basal glucose or insulin concentrations or the glucose disappearance or insulin response to an intravenous bolus of glucose in

fasted monkeys. If insulin secretion and its peripheral actions are modulated in a similar manner in the rhesus monkey as in women, the present results suggest that the reported insulin resistance in women with hyperandrogenism may not be a result of hyperandrogenism alone. A similar conclusion has recently been reported in a study of antiandrogens and insulin resistance in obese women with polycystic ovarian disease.[8]

Monkeys chronically exposed to elevated estrone and estradiol had a lower insulin response to the intravenous glucose bolus. C-peptide concentrations paralleled the insulin response. Although the insulin and C-peptide concentrations of the estrone-treated monkeys were not significantly different from the corresponding concentrations in control and androstenedione-treated animals, a lower insulin response to glucose was observed in both test periods. The glucose disappearance rate was significantly slower in both test periods in the estrone-treated monkeys compared with either the control or androgen-treated monkeys. Furthermore, the ratio of insulin area to glucose area was lowest for the estrone-treated animals in both test periods. These results suggest that chronic elevation of the estrone and estradiol concentrations may modulate the pancreatic response to glucose, even though the estrone and estradiol concentrations were less than three times higher than in the early follicular phase[9] (Table I).

It is difficult to compare the observed estrogen effect in the monkey with similar studies in humans or monkeys, since (1) different estrogen preparations were used, (2) the dosages were usually higher and circulating estrogen concentrations were not measured, and (3) the duration of such studies was usually for shorter time periods. Nevertheless, the present results were not anticipated since estrogens have been observed to have either no effect or a stimulatory effect on the insulin response to glucose.[12, 14] The smaller variation in insulin and C-peptide concentrations in the estrone-treated animals in response to glucose might provide the explanation. Insulin responses to glucose are dependent on the prior metabolic history of the animal.[15] It may be that monkeys chronically treated with estrogen have a more consistent dietary pattern than that of cycling control or androgen-treated animals,[16, 17] resulting in a more consistent insulin response among the estrogen treatment group.

We acknowledge the excellent technical assistance of Anna Da Silva in the performance of the insulin RIAs, Kathy Petzgold in the C-peptide analysis, and H. Traikov in the RIA of androstenedione, testosterone, and estradiol.

A new look at uterine muscle contraction

Mary E. Carsten, Ph.D., and Jordan D. Miller, M.D.
Los Angeles, California

Recent progress in our understanding of uterine smooth muscle contraction is reviewed. We no longer believe that actin-myosin interaction in the myometrium occurs through activation of the thin filament; but it is triggered by calcium-dependent phosphorylation of myosin in the thick filament. Calcium is now thought to originate from both extracellular and intracellular sources. Calcium can enter the cell through either a voltage- or a hormone-controlled calcium channel. The intracellular source of calcium is the sarcoplasmic reticulum. The effect of oxytocin in human labor is no longer considered the result of increased circulating oxytocin but rather of increased oxytocin receptors. In contrast, the contractile action of some prostaglandins is related to increased prostaglandin formation at human parturition. The step between hormone binding and cellular action is mediated by second messengers. The uterine-relaxing action of cyclic adenosine monophosphate is now thought to be limited to the inhibition of myosin phosphorylation. Recently discovered second messengers for contraction of the myometrium are phosphoinositides; their turnover causes calcium release from the sarcoplasmic reticulum. Guanine nucleotides are thought to be modulators of these two second messengers. (Am J Obstet Gynecol 1987;157:1303-15.)

The past decade has seen the following three new developments contribute to our understanding of smooth muscle contraction and in particular to uterine muscle contraction: (1) The actin-myosin interaction in uterine smooth muscle was shown to be different from that in skeletal muscle; (2) the dominant role of intracellular calcium in smooth muscle contraction was firmly established; and (3) a new second messenger, inositol trisphosphate, was discovered. The common denominator for these reactions is calcium. In this review, recent findings will be discussed, and molecular mechanisms will be reviewed as far as they are known. Since not all experimental data are available for the myometrium, at times we will have to refer to other smooth muscles. This is with some misgivings because where detailed studies have been done, differences have been found, even between arteries from various locations. Nevertheless, we have made progress in our understanding of normal events in myometrial contraction.

Contraction

Smooth muscle structure. While it had been known for many years that actin and myosin were present in smooth muscle, it was thought that smooth muscle contraction was similar to that of skeletal muscle, which is represented by the sliding filament model. Arrays of thick protein filaments containing the protein myosin interdigitate with arrays of thin filaments containing the protein actin. In contraction the filaments move past each other because of actin-myosin interaction without a change in length of the individual filament, but the muscle as a whole changes its length. Interaction of actin and myosin occurs through the myosin cross-bridges, protrusions from the myosin filament that reversibly bind to actin. The energy for contraction comes from adenosine triphosphate (ATP) hydrolysis. In skeletal muscle the interaction of actin and myosin is inhibited by the presence of the tropomyosin-troponin complex in the thin filament. The inhibition is removed when troponin binds calcium, which causes a steric shift of the complex. Attempts to visualize thick filaments in smooth muscle were unsuccessful for many years. This was partly from technical difficulties and partly from the lower myosin content of smooth muscle.[1] In smooth muscle, the alignment of the filaments is less regular; hence no cross-striations are observed. The thin filaments can be arranged in parallel with the cell axis, in arrays of various shapes, and in rosettes when in association with myosin, or at random.[2, 3] The actin filaments connect through dense bodies with the plasma membrane. This modification allows for many features characteristic of smooth muscle—its ability to shorten to less than 50% and lengthen to more than twice its resting length, greater force, and low velocity of contraction.

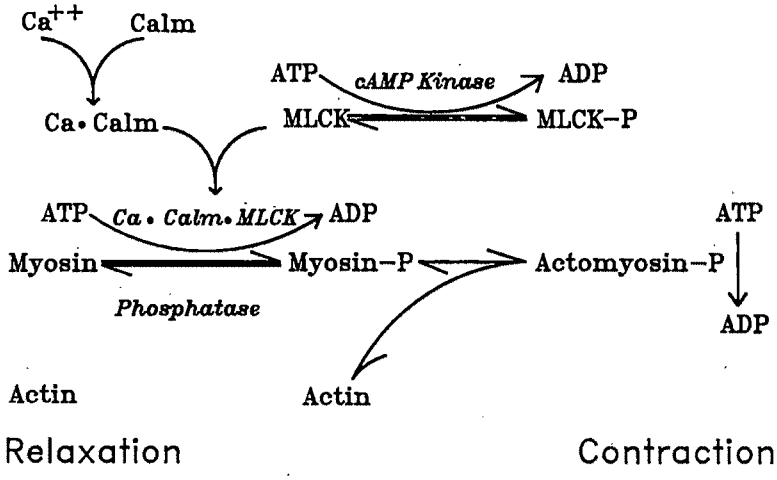

Fig. 1. Diagram of contraction-relaxation cycle of smooth muscle. (*Calm* = Calmodulin; *cAMP kinase* = cAMP-dependent protein kinase; *MLCK* = myosin light-chain kinase; *MLCK-P* = phosphorylated myosin light-chain kinase; *Myosin-P* = phosphorylated myosin; *Actomyosin-P* = phosphorylated actomyosin; *ADP* = adenosinediphosphate; *ATP* = adenosine triphosphate.)

The actin-myosin interaction in smooth muscle. In smooth muscle, most of the evidence indicates that troponin plays only a minor role, if any, in the contraction-relaxation cycle. Myosin consists of four polypeptide chains, two heavy chains and two light chains. In smooth muscle contraction, the 20,000 molecular weight myosin light chain is phosphorylated by the enzyme myosin light-chain kinase when the calcium concentration rises. Only when phosphorylated can the myosin light chain interact with actin. The reaction requires the protein calmodulin; the calcium-calmodulin complex then binds to myosin light-chain kinase for activation. When the calcium level decreases, the calmodulin dissociates from the myosin light-chain kinase and the myosin light-chain kinase becomes inactive. Dephosphorylation of the myosin light chain occurs at a steady rate by a phosphatase.[4, 5] This reaction has been demonstrated in vitro and in intact smooth muscle.[6] The activity of the myosin light-chain kinase is modulated by a cyclic adenosine monophosphate (cAMP)–dependent protein kinase. This protein kinase catalyzes phosphorylation of myosin light-chain kinase.[7] The phosphorylated myosin light-chain kinase has only a weak affinity for the calcium calmodulin complex, thus becoming inactive. Dephosphorylation of myosin and relaxation follow.[6, 8] This reaction sequence is illustrated in Fig. 1.

In the myometrium, myosin light-chain phosphorylation and dephosphorylation were demonstrated for the contraction-relaxation cycle.[9] Serine and threonine residues of the myosin light chain were phosphorylated.[10]

Less popular hypotheses, which may well play a role as auxiliary mechanisms for smooth muscle contraction, focus on calcium stimulation acting on the thin filament. One hypothesis involves the binding of the protein leiotonin to actin[11], the other, the calcium-dependent regulation by the protein caldesmon, present in the thin filaments.[2] No attempts have been made so far to demonstrate these proteins in the myometrium.

Pharmacomechanical coupling

The events leading to muscle contraction start at the cell membrane with a stimulus. The stimulus initiates an action potential, which is followed by a contraction. This is called electromechanical coupling and is a means of excitation-contraction coupling in skeletal muscle. It has been found that in smooth muscle, electromechanical coupling does not fully explain observed phenomena.[12] In smooth muscle, there is not always an action potential. There can be either electrical or hormonal stimulation. Hormone binding to a receptor at the cell surface can activate a chain of events that ultimately lead to muscle contraction. This is called pharmacomechanical coupling.[13] The search for its mechanism and some of the answers are discussed in the following sections.

The role of calcium

The smooth muscle cell membrane. A diagram of the smooth muscle cell is shown in Fig. 2, and the actin and myosin filaments are seen. At 10^{-8} to 10^{-7} M calcium, the muscle is relaxed, and at 10^{-6} M calcium, the filaments interact and the muscle contracts without changing filament length. From where does the calcium for contraction come? It has long been known that part of the calcium comes from outside the cell. The calcium concentration outside the cell in the interstitial fluid is 10^{-3} M, that is, 10,000-fold higher than that inside the cell. Although there is an electrochemical gradient, calcium does not rush into the cell at rest because of the

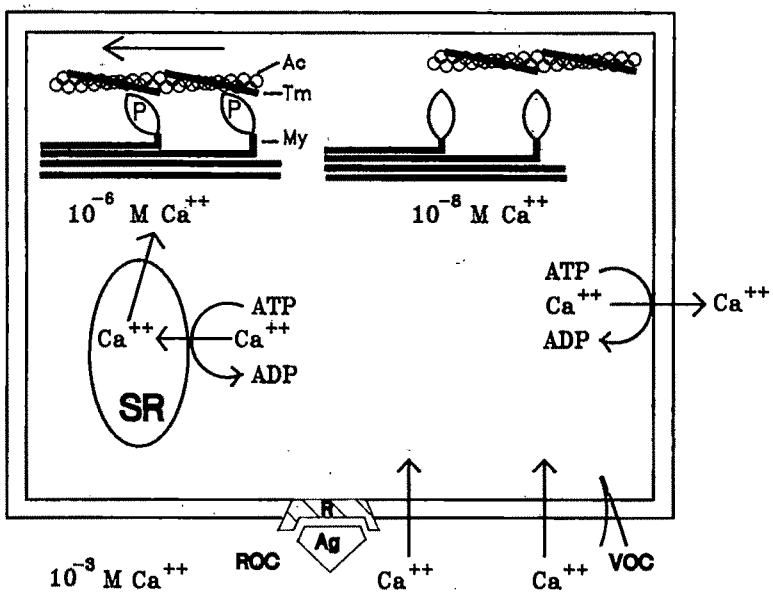

Fig. 2. Calcium sources for myometrial contraction. On top, sliding filament of muscle contraction *(left)* and relaxation *(right)*. low calcium permeability of the cell membrane. Calcium can enter the cell through an ion channel with an action potential. Calcium binds reversibly to a specific site at or near the surface of the channel. Subsequent movement of the calcium ion is determined by current flow and the extracellular concentration of calcium.

Calcium channels. Some chemical agents that inhibit contraction have been found to directly block calcium entry. They are called calcium channel blockers, or calcium entry blockers; they bind to the cell membrane within the membrane calcium channel.[14] They make up a wide range of structures ranging from inorganic ions such as lanthanum to some organic compounds. The more interesting ones are the dihydropyridines, nitrendipine, nifedipine, nicardipine, and other unrelated compounds such as diltiazem, verapamil, and D 600. Some of the latter have been found to have additional action in the myometrium.[15] Observations on muscle strips from the parturient rat uterus showed that D 600 and other calcium entry blockers abolished spontaneous contractions and reduced the force of electrically evoked contractions. However, D 600 did not block the tonic contraction evoked by prostaglandin (PG) $F_{2\alpha}$.[16, 17] These experiments suggested the presence of another type of calcium channel, namely, one controlled by hormones. It was subsequently shown in rabbit aorta that the amount of calcium influx on maximal stimulation by potassium or norepinephrine was dissimilar and each was less than the calcium influx when both were applied simultaneously. This led to the suggestion that an additional set of calcium channels could be opened by norepinephrine after maximal calcium influx caused by potassium.[18] Furthermore, D 600 preferentially inhibited potassium-activated channels, and in general, higher concentrations of calcium entry blockers are required to block the receptor-operated channel than the voltage-operated channel. Clinically, calcium channel blockers produce adequate relaxation and have been used to inhibit spontaneous contractions in premature labor[19-21] and myometrial hyperactivity in primary dysmenorrhea.[22-24]

Calcium efflux through the cell membrane. The calcium that entered the cell for contraction must eventually be pumped out of the cell. The energy requiring transport of calcium across membranes is mediated by enzymes, the so-called calcium and magnesium adenosine triphosphatases (Ca,Mg-ATPase), because these enzymes split adenosine triphosphate (ATP) and require calcium and magnesium for their activation. The ATPase of the cell membrane is stimulated by the protein calmodulin[25] and inhibited by the chemical vanadate.[26]

In cardiac muscle an important mechanism for moving calcium across the cell membrane is Na^+-Ca^{++} exchange. This mechanism works by removing calcium from the inside of the cell in exchange for incoming sodium. The Na^+-Ca^{++} exchange has been observed in some smooth muscles including the uterus.[27-30] However, the Na^+-Ca^{++} exchange appears to be of low magnitude in smooth muscle, which may be from technical difficulties in experimentation. Its physiologic significance is debated.[18]

Role of the sarcoplasmic reticulum. Recent observations have shown that the influx of calcium with an action potential is insufficient to activate fully the contractile mechanism and sustain maximum contraction

of smooth muscle.[31] Much of the required calcium comes from intracellular stores, but there are quantitative differences between various smooth muscles.

In skeletal muscle there is an abundant system of intracellular channels or tubules, called the sarcoplasmic reticulum. This system stores calcium in relaxation. On an impulse conducted from the cell membrane, this calcium is rapidly released during contraction. This mechanism is useful because of the large size of the skeletal muscle cell and the speed of contraction. In contrast, the smooth muscle cell is much smaller than the skeletal muscle cell and contractions are slow. Hence the role of the sarcoplasmic reticulum in smooth muscle contraction was questioned. Early observations demonstrated a less abundant sarcoplasmic reticulum in smooth muscle cells.[32, 33] However, recent studies with the electron microscope have shown a sarcoplasmic reticulum similar to that in skeletal muscle.[34] The sarcoplasmic reticulum is estimated to occupy about 1.5% to 7.5% of the cell volume of the smooth muscle cell and is particularly abundant in some blood vessels and in pregnant or estrogen-treated uterus.[34] It has been demonstrated that in vascular smooth muscle, in calcium-free solution, and in the presence of lanthanum, which blocks passage of calcium through the cell membrane, intracellular stores of calcium are sufficient to elicit maximal contraction through recycling of intracellular calcium stores.[35] Ultrastructural studies that use electron-probe analysis have shown high calcium concentrations in the sarcoplasmic reticulum of relaxed smooth muscles. From these findings it was concluded that the sarcoplasmic reticulum and not the cell membrane is the organelle primarily responsible for the physiologic regulation of the cytoplasmic calcium.[31] This hypothesis is also borne out by physiologic and biochemical observations. It is presently thought that mitochondria play no role in the regulation of cytoplasmic calcium at physiologic levels.[37]

In relaxation calcium is sequestered by the sarcoplasmic reticulum. This mechanism for reducing the intracellular calcium concentration is in addition to the extrusion of calcium through the plasma membrane previously discussed.

Calcium uptake into the sarcoplasmic reticulum. Calcium uptake into the sarcoplasmic reticulum will be discussed first. More is known about calcium uptake than about calcium release, since the former has been easier to study.

The transport of calcium into the sarcoplasmic reticulum can best be demonstrated on the subcellular level in microsomal preparations. The techniques for isolating microsomal preparations are based on the procedures used for the preparation of the sarcoplasmic reticulum of skeletal muscle. They were modified because of the large amount of connective tissue in smooth muscle that prevents easy isolation of smooth muscle components. Furthermore, smooth muscle contains much more cell membrane than does skeletal muscle because of the smaller size of the smooth muscle cell. Thus it is harder to prepare pure sarcoplasmic reticulum from the smooth muscle cell. The degree of purity of the preparation is difficult to document because there are no unique markers.[38, 39]

In our laboratory we have isolated sarcoplasmic reticulum from term pregnant bovine myometrium and human uteri obtained at cesarean hysterectomy.[40-42] Under the electron microscope our sarcoplasmic reticulum preparation shows vesicles of about 1000 Å (100 nm) diameter.[40] In the presence of ATP and calcium, the sarcoplasmic reticulum preparations accumulate calcium on the inside of the vesicles, that is, they take up calcium from solution. The calcium uptake increases with an increased amount of calcium in solution[43] and is stimulated by oxalate. The process is temperature-dependent and ATP is required. This in vitro process of calcium removal from solution and transport into a storage area would cause in vivo muscle relaxation.

Adenosine triphosphatase. Parallel with calcium uptake is ATPase activity. A Ca,Mg-ATPase in the sarcoplasmic reticulum membrane breaks down ATP to adenosine diphosphate (ADP) by removing the terminal phosphate group.[12] This Ca,Mg-ATPase has different characteristics from the ATPase of the cell membrane. These characteristics serve to identify the origin of the isolated microsomal preparations. In contrast to the ATPase of the cell membrane, the ATPase of the sarcoplasmic reticulum is not sensitive to stimulation by calmodulin or inhibition by vanadate.[25, 26, 44] On the molecular level the ATPases of sarcoplasmic reticulum and cell membrane differ in molecular weight (sarcoplasmic reticulum 100,000 to 110,000; cell membrane 130,000) as shown by electrophoresis of the phosphorylated intermediate.[45, 46] With tryptic digestion, little difference could be found between the molecular weight of the ATPase of aortic smooth muscle and that of skeletal muscle. However, there are immunologic differences.[47] The tryptic digestion pattern of the ATPase of the sarcoplasmic reticulum is different from that of the cell membrane ATPase.[47]

Mechanism of calcium transport. To understand the events that occur in the transport of calcium through the membranes of the sarcoplasmic reticulum, it is advantageous to examine partial reactions, since these can be more easily interpreted. Several steps in the cycle of calcium uptake into sarcoplasmic reticulum vesicles and calcium release and the mechanism of action of the Ca,Mg-ATPase have been recently elucidated.

The first step in calcium transport is the binding of calcium to the outside of the vesicular membrane of sarcoplasmic reticulum. Two types of calcium binding sites were found with association constants of 8 and 0.1 ($\times 10^6\ M^{-1}$). The number of binding sites was four and 10 nmol/mg of protein, respectively. The high-affinity binding site appears to be part of the transport ATPase;

the presence of a second binding site may indicate that calcium serves an additional function.[48]

The use of magnesium sulfate as a tocolytic agent in the treatment of premature labor[49-51] is well known. It has been shown that Mg^{++} abolishes contractions in uterine muscle strips.[52] In the presence of 5 mM Mg^{++}, the maximum number of low-affinity calcium sites was reduced to half, whereas the high-affinity calcium binding sites were not affected by Mg^{++}.[48] Whether the changes observed in vitro correlate with the in vivo action of Mg^{++} remains to be documented.

The next step in calcium transport is the formation of a high-energy intermediate in the presence of ATP and calcium. This is demonstrated by showing a phosphorylated ATPase. Using [^{32}P]ATP, we obtained results that document phosphorylation of the ATPase,[43] which were consistent with the following scheme, modeled after that presently established for calcium transport in skeletal muscle.

$$Ca_{out} + E + ATP \rightleftharpoons Ca \cdot E \cdot P + ADP$$
$$Ca \cdot E \cdot P \rightleftharpoons E + P + Ca_{in}$$

where E is the 110,000 molecular weight ATPase enzyme. E binds calcium plus ATP with activation of the enzyme. The formation of an intermediate, Ca · E · P, results from the binding of a terminal phosphate, P, of ATP to the aspartyl residue of the ATPase. The ATP is split, ADP is released, calcium is then transported to the inside of the vesicles, and phosphate is released.

Calcium release. The reverse process, the release of calcium from the sarcoplasmic reticulum vesicles, does not require energy and leads in vivo to contraction. Experiments with microsomal vesicles have shown that the vesicles are relatively impermeable to calcium with a half time of 100 minutes at 37° C. This means that it will take 100 minutes for half the accumulated calcium to diffuse out of the vesicles. However, this can be speeded up by use of an ionophore. Ionophores move calcium through a membrane down the concentration gradient. The release of calcium with an inophore shows that the calcium is inside the vesicles[53]; however, this is not a physiologic mechanism. Therefore we are left with the question, what is the physiologic mechanism for calcium release?

Hormonal calcium mobilization. The uptake and release of calcium can be inhibited or enhanced by various agents. As shown in partially purified microsomal preparations in our laboratory, the uterine contractile prostaglandins E_2 (PGE_2) and $F_{2\alpha}$ ($PGF_{2\alpha}$) inhibited calcium uptake and enhanced calcium release; oxytocin also inhibited calcium uptake. Consistent with its pharmacologic action, PGE_2 was more potent than $PGF_{2\alpha}$. Much greater effects of oxytocin and slightly greater effects of $PGF_{2\alpha}$ were observed in microsomes derived from pregnant uteri than in those from nonpregnant uteri.[41, 42, 54, 55] The increase in free calcium is a prerequisite for contraction. Similar effects of $PGF_{2\alpha}$ were recently observed in vascular smooth muscle cells.[56] The release of calcium from intracellular calcium stores by prostaglandins is further supported by experiments showing prostaglandin-induced contraction of rat uterine horns in calcium-free medium.[57] It is unclear whether this is a direct effect of prostaglandins or whether it is mediated through a messenger.

Hormonal stimulation and hormone receptors

The two physiologic hormones that cause uterine contractions are oxytocin and prostaglandin. Oxytocin is the preferred pharmacologic agent for induction of labor because of its high specificity in contracting the uterus. However, the physiologic role of these two hormones in the onset of human labor is controversial, and the picture is muddled by great differences between species. In the context of this discussion, it is unnecessary to go into arguments of which is the more important.

Oxytocin. Some workers have shown a rising trend in oxytocin concentration in the maternal plasma with gestation. This trend increased toward the end of pregnancy.[58, 59] However, technical difficulties with the assay, fluctuating patterns, and wide scatter of obtained oxytocin values make these results questionable. More recent work showed no rise in plasma oxytocin concentration until late in the second stage of labor.[60, 61]

An alternative explanation for the effect of oxytocin would be a rise in oxytocin receptors. This is manifested by increased sensitivity to oxytocin. Increased sensitivity of the myometrium to oxytocin with advancing pregnancy, especially toward the very end of pregnancy, has long been known.[62] Indeed, it was shown that the sensitivity to oxytocin correlated with preterm and postterm delivery, with women who delivered prematurely having the highest sensitivity to oxytocin.[63]

Specific receptors for oxytocin have been identified in the rat,[64, 65] ewe,[66] rabbit,[67] and human uterus.[68, 69] In binding experiments with purified subcellular membrane fractions, the oxytocin receptors were found to be located in the myometrial cell membrane. The dissociation constant was calculated to be in the range of 2 to 3 nM.[64, 66, 67] The concentration of oxytocin receptors rises toward the end of pregnancy, is maximal during labor, and then declines.[64] In subcellular preparations from a human uterus, there was also an increase in oxytocin receptor concentration with gestational age, as well as some increase in binding affinity at term.[68] Similar changes in oxytocin receptor concentration were found in human uteri at various stages of gestation and in labor, with lower values before the onset of labor and in failed induction of labor with oxytocin.[69] Furthermore, the concentration of oxytocin receptors appears to be regulated by estrogen and progesterone, at least in the rat and rabbit, with estrogen increasing the number of oxytocin receptors and progesterone inhib-

iting this increase.[64, 70, 71] These findings correlate with observed physiologic function and suggest that the increase in uterine sensitivity to oxytocin is caused by an increase in myometrial oxytocin binding sites.

Prostaglandins. Unlike oxytocin, which is a circulating hormone, prostaglandins originate at or near their site of action, that is, in the endometrial and myometrial cell. Therefore one would expect differences in the physiologic action of these two hormones. Early work indicated that administration of PGE_2 and $PGF_{2\alpha}$ and prostaglandin analogs by various routes causes contraction of the pregnant and nonpregnant uterus and can initiate labor or abortion at any stage of gestation.[72, 73]

Prostaglandins play an important role in both the nonpregnant and pregnant uterus as evidenced by physiologic, pathologic, and pharmacologic findings. During the menstrual cycle, high concentrations of both PGE and PGF were found in the human myometrium during the late proliferative phase, coinciding with ovulation. After ovulation the concentration of PGE gradually declined and stayed low, whereas the PGF concentration showed a second peak during the late secretory phase, approximately coinciding with the onset of menstruation.[74] However, in humans and primates, prostaglandins have no luteolytic effect, in contrast to domestic animals.[75, 76] High levels of $PGF_{2\alpha}$ and PGE were found to be present in menstrual fluid collected from women suffering from primary dysmenorrhea.[77] Prostaglandin synthesis inhibitors can stop menstrual cramps and pain in primary dysmenorrhea.[78]

Prostaglandins are detected by radioimmunoassay in the amniotic fluid at about midpregnancy, and their concentration rises through the remainder of pregnancy and into spontaneous labor, with PGE_2 levels higher than those of $PGF_{2\alpha}$.[79] Their concentration in the amniotic fluid, as well as that of arachidonic acid, are higher during labor than before labor and increase with labor.[80] The levels of PGF were found to be higher in women going into spontaneous labor than in women requiring oxytocin induction.[81, 82] However, measurement of prostaglandins in the amniotic fluid is influenced by the mode of obtaining the samples; results are higher in samples collected at amniotomy than in those obtained by amniocentesis.[83]

The measurement of prostaglandins in peripheral plasma is even more difficult than that in amniotic fluid because of their low concentration, the ability of blood platelets to synthesize prostaglandins, and the destruction of prostaglandins by one passage through the lungs.[84] More reliable measurements are obtained by monitoring a prostaglandin metabolite, 13,14-dihydro-15-keto-PGF, which is present in much higher concentration and not synthesized in platelets. With these measurements no increase in prostaglandin concentration in the peripheral blood was noted up to the onset of labor.[85] On the other hand, 13,14-dihydro-15-keto-PGF levels have been found to rise concomitant with cervical ripening without uterine activity before the onset of labor.[86] Taken together these findings lead to the concept that increased synthesis of prostaglandins plays a dominant role in human parturition.

The events that lead to the formation of prostaglandins in human parturition begin in the fetal membranes (amnion and chorion) and also in the decidua. Prostaglandin production is greatest in the amnion, followed by the chorion, and finally the decidua.[87] The first step is the release of free arachidonic acid. Arachidonic acid is the obligatory precursor of the prostaglandins of the "2" series. Arachidonic acid is not stored in human tissues, but human fetal membranes accumulate arachidonic acid in esterified form in the form of glycerophospholipids. The major pathway of arachidonic acid release is by phospholipase A_2 action. This enzyme breaks down glycerophospholipids in the "2" position. The end products of hydrolysis are free fatty acid and lysoglycerophospholipid. Lysoglycerophospholipids are cytolytic agents. They break down cell membranes and also lysosomal membranes inside the cell. Lysosomes contain more phospholipase. Its release causes accelerated release of arachidonic acid and thus accelerated prostaglandin synthesis from preformed glycerophospholipids in the fetal membranes. The preferred substrate for phospholipase A_2 in the fetal membranes is phosphatidyl ethanolamine, which has arachidonic acid in the "2" position.[80, 88, 89] PGE_2 and $PGF_{2\alpha}$ are subsequently formed from arachidonic acid in a multistep process, the first step of which is catalyzed by the enzyme cyclooxygenase.[84] The intermediate endoperoxide and thromboxane also contract the uterus. A secondary pathway of arachidonic acid mobilization starts from phosphatidylinositol. Its breakdown requires three enzymes, phospholipase C, diacylglycerol lipase, and monoacylglycerol lipase.[89, 90]

The stimulus for increased prostaglandin formation in the fetal membranes at the onset of human parturition may be estrogens.[91] Estradiol was shown to stimulate cyclooxygenase activity in the rat uterus[92, 93] and aortic smooth muscle cells.[94] Stimulation of prostaglandin synthesis by oxytocin has been observed in decidua parietalis but not in decidua vera from the membranes or the myometrium.[95, 96] There is some evidence that calcium plays a role in arachidonic acid mobilization followed by prostaglandin production in amnion tissue.[89]

There is a striking association between premature labor and intrauterine, endocervical, and urinary tract infection. It has been shown that many of the organisms that cause these infections have phospholipase A_2 activity.[97] This would lead to increased release of arachidonic acid from preformed glycerophospholipids in the fetal membranes, followed by prostaglandin biosynthesis and preterm labor.

Inhibitors of prostaglandin synthesis may delay par-

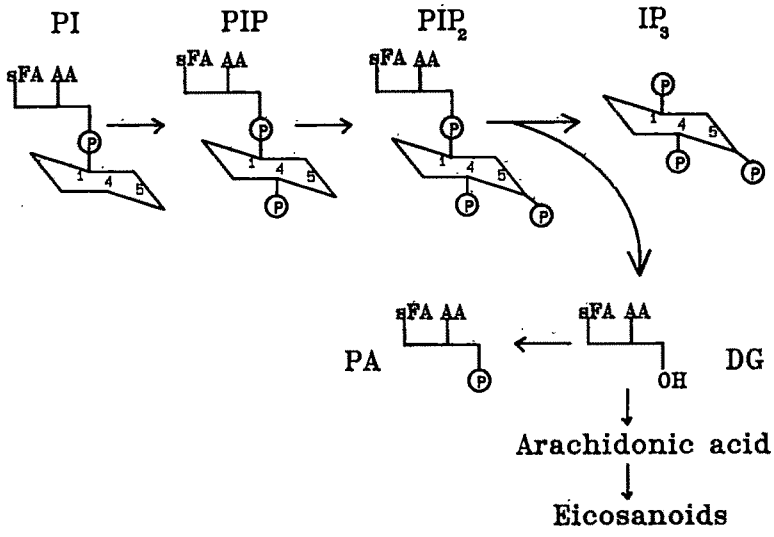

Fig. 3. Pathway of phosphatidylinositide metabolism. Eicosanoids comprise prostaglandins, thromboxane, and leukotrienes.

turition as shown in experimental animals.[98, 99] Aspirin and indomethacin are potent inhibitors of cyclooxygenase, which catalyzes the conversion of arachidonic acid to prostaglandins. In women, prolonged intake of large doses of aspirin can lengthen pregnancy,[100, 101] and administration of indomethacin can extend induction-abortion time in midtrimester abortion.[102] However, the use of these agents for treatment of preterm labor is disputed because they may cause premature closure of the ductus arteriosus, and aspirin, in particular, may lead to prolonged platelet dysfunction and bleeding.[103-106]

PGE_2, $PGF_{2\alpha}$ and some of their derivatives are useful tools in terminating pregnancy as in cases of an anencephalic or dead fetus[107, 108] where oxytocin is ineffective. They are less suited for the initiation of labor because of their nonspecificity. Thus they may contract other smooth muscles such as those of the blood vessels and intestinal tract. This may give rise to undesirable side effects, for example, nausea, vomiting, and diarrhea.

Overwhelming evidence in the literature suggests that there is interaction of prostaglandins and oxytocin and furthermore that the presence of prostaglandins is obligatory for a maximal response to oxytocin. Thus an increase in oxytocin sensitivity is prevented by administration of prostaglandin synthetase inhibitors.[109] In vivo, prostaglandins can lower the myometrial threshold to oxytocin.[110] In vitro, it has been shown that prostaglandins are needed for oxytocin action. Indomethacin, meclofenamate, and R-805, all potent inhibitors of prostaglandins synthetase (cyclooxygenase), antagonize the contractile effects of oxytocin but not of $PGF_{2\alpha}$ on the isolated uterus of the rat and humans.[111-116] Contraction of pregnant and nonpregnant human uteri, abolished by the addition of indomethacin, was reestablished in response to $PGF_{2\alpha}$ but not to oxytocin.[113]

In contrast to oxytocin, PGE and $PGF_{2\alpha}$ receptors change little in the human myometrium during pregnancy and labor. This would be in agreement with the small observed change in sensitivity to PGE through pregnancy and labor. Furthermore, there appears to be little change in prostaglandin receptors during the menstrual cycle. A single class of high-affinity binding sites was demonstrated for PGE_1 with an apparent equilibrium dissociation constant (K_D) of 3.65 nM for PGE_1 and 26.9 nM for $PGF_{2\alpha}$.[117]

In purified subcellular fractions from bovine and human pregnant myometrium, prostaglandin receptors were found in the cell membrane fraction and the sarcoplasmic reticulum, which is not surprising since prostaglandins are transported by the circulation and also originate inside the cell. The affinity of cell membrane and sarcoplasmic reticulum for PGE_2 was the same. The average K_D for PGE_2 and PGE_1 was 2.50 to 3.05 nM, with the same receptor specific for both these prostaglandins. $PGF_{2\alpha}$ and a series of inactive prostaglandins exhibited low competitive effects on PGE_2 binding.[118] The presence of the same receptor for PGE_1 and PGE_2 but of separate receptors for PGE and $PGF_{2\alpha}$ has been observed by many investigators.[117-120]

We may draw the conclusion that the physiologic changes that lead to human parturition are related to changes in the number of oxytocin receptors and to increased biosynthesis of prostaglandins.

Gap junctions. In addition, gap junctions appear in the myometrium of various animals during parturition and in humans during term and preterm labor. Gap junctions are areas of low resistance to the flow of cur-

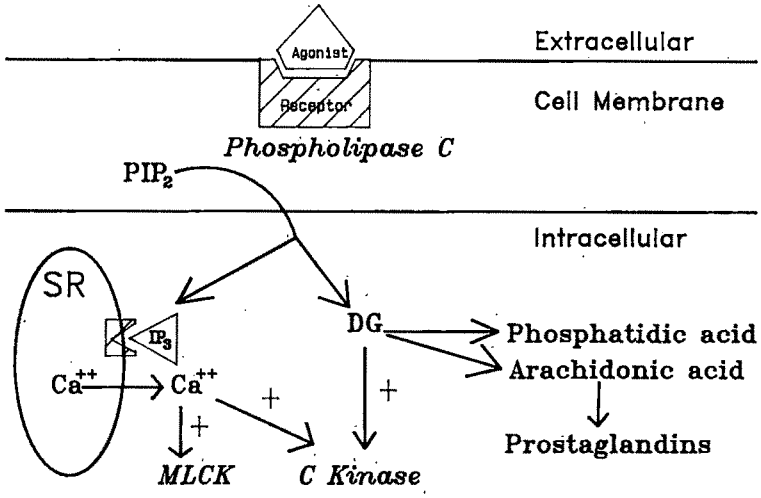

Fig. 4. Agonist-dependent second messengers: inositoltrisphosphate, calcium, and diacylglycerol. Agonist receptor-binding activates phospholipase C to hydrolyze phosphatidylinositol 4,5-bisphosphate *(PIP_2)* to inositol 1,4,5-trisphosphate *(IP_3)* and diacylglycerol *(DG)*. *MLCK* = Myosin light-chain kinase; *C Kinase* = protein kinase C. MLCK and C Kinase phosphorylate various proteins, leading to biologic responses.

rent. These cell-to-cell contacts serve to couple cells and allow synchronized muscle contractions in labor. Formation of gap junctions, at least in the rat and sheep, appears to be modulated by the interaction of various hormones, such as estrogen, progesterone, and prostaglandins.[121-123]

Second messengers

Cyclic AMP. The events leading from hormone binding to hormone action are mediated by so-called second messengers. Hormones bind to specific receptors at the outside of the cell membrane. The distribution and ligand specificity of the receptors determine the tissue response and production of a second messenger. The second messenger then transposes nonspecifically to the substrate inside the cell.

Adenosine-3′:5′-monophosphate (cyclic adenosine monophosphate, cAMP) has been identified as such a second messenger. Originally it was demonstrated that in the liver epinephrine releases cAMP, which in turn activates phosphorylase.[124] Based on this finding, the concept evolved that cAMP was the messenger for a multitude of other hormones. The action of cAMP is very well characterized as a messenger for epinephrine or isoproterenol, that is, for β-adrenergic agents. The uterine-relaxing action of β-adrenergic agents is well known. Indeed, some other relaxing agents have been shown to increase cAMP in the uterus, notably the anesthetic halothane.[125] Older theories of muscle contraction and relaxation, such as the Ying Yang theory, suggested that β-adrenergic agents brought about relaxation through the messenger cAMP and contractile agents work through cyclic guanosine monophosphate (cyclic GMP, cGMP).[126]

It was assumed that all relaxing agents work through cAMP and all contractile agents work through cGMP. Evidence has now accumulated to show that cAMP may not be an obligatory mediator of relaxation of the uterus. This hypothesis is based on the lack of correlation between the relaxing action of hormonal or pharmacologic agents and cAMP levels in the uterus or between tension and cAMP.[127, 128] Relaxation of the uterus produced by isoproterenol under various conditions in vitro does not always correlate with changes in membrane potential[129] or in tissue levels of cAMP.[130, 131] An explanation forwarded is that the increase in cAMP is localized and too small to be detected by chemical analysis of total tissue content of cAMP.[128] With whole-uterine muscle and a microsomal preparation from rat uterus, specific binding and cAMP production showed parallel dose-response curves as did relaxation.[132] However, it must be hypothesized that <10% of maximal cAMP production accounts for 50% of relaxation; this has not been proved.

Additional evidence for the lack of correlation of cAMP and relaxation comes from work on the role of prostaglandins in cAMP synthesis. In tissue slices PGE_1 and PGE_2, which contract the uterus, increased cAMP levels.[133] One might argue that results were obscured because of compartmentalization. However, in our laboratory, using uterine homogenates and partially purified subcellular fractions, PGE_2 and $PGF_{2\alpha}$, also elicited increased synthesis of cAMP, as did isoproterenol.[134] The claim that cAMP enhances calcium uptake in subcellular preparations[135, 136] was also untenable. With the use of purified microsomal preparations derived from the sarcoplasmic reticulum,[42] our laboratory showed that neither cAMP nor the protein kinase catalytic subunit increased calcium uptake.[134] Thus it appears to date that if cAMP has a relaxing action on the uterus, its mechanism is not in enhancing storage of calcium in intracellular organelles.

More recent evidence again involves cAMP in relaxation. cAMP may function primarily at the level of the actin-myosin interaction (see above and Fig. 1): in the phosphorylation of the enzyme myosin light-chain kinase by the cAMP–dependent protein kinase. This inhibits myosin light-chain kinase and thus myosin light-chain phosphorylation, thereby reducing actin-myosin interaction.

Cyclic GMP. Attempts to correlate cyclic guanosine monophosphate (cGMP) levels specifically with either contraction or relaxation have failed. Thus in carbachol-induced contractions, no change in cGMP was found in the rat uterus. In guinea pig myometrium, cGMP was increased, but in carefully timed experiments, contractions were shown to precede the rise in cGMP, and no changes in cAMP were observed.[137] Furthermore, no correlation between cGMP elevation and contraction or relaxation of rat myometrium could be established.[138]

Phosphoinositides. Since the nucleotide mechanism is inadequate to explain the link between hormone binding and contraction, what causes elevation of intracellular free calcium and contraction of the uterine smooth muscle cell? There is mounting evidence that binding of agonists to receptors, which leads to calcium mobilization, functions by hydrolyzing phosphoinositides.[139, 140] The phosphoinositides are minor components of cell membranes. Their structure is shown in Fig. 3. A phosphodiesterase (phospholipase C) hydrolyzes phosphatidylinositol 4,5-bisphosphate to diacylglycerol and D-myoinositol-1,4,5-trisphosphate (inositol trisphosphate). The inositol trisphosphate acts to mobilize intracellular calcium from the endoplasmic reticulum or sarcoplasmic reticulum, as it is called in smooth muscle (Fig. 4). Diacylglycerol activates protein kinase C, which phosphorylates various proteins.[139] The inositol trisphosphate is then broken down stepwise to inositol by phosphatases which are stimulated by diacylglycerol. In the cell membrane inositol is used for stepwise resynthesis of phosphatidylinositol. These reactions have been shown in many tissues.

Two experimental approaches are used to demonstrate these reactions. One is to demonstrate increased metabolites of phosphoinositides on receptor-agonist interaction; the other is to show an increase in free calcium in permeabilized cells or sarcoplasmic reticulum preparations on exposure to inositol trisphosphate. Increased hydrolysis of phosphoinositides and release of inositol trisphosphate have been observed in uterine strips on stimulation with oxytocin or carbachol.[141] In our laboratory, addition of inositol trisphosphate caused release of calcium from isolated sarcoplasmic reticulum preparations. This calcium release was concentration dependent, and at the highest concentration used, amounted to 40% of calcium releasable by an ionophore.[142] In permeabilized cells from the mesenteric artery, the amount of calcium released by inositol trisphosphate was sufficient to elicit a contraction.[143] Thus one is tempted to suggest that inositol trisphosphate may be the link between agonist-receptor binding, intracellular calcium rise, and uterine smooth muscle contraction.

Although there is strong evidence for the involvement of phosphoinositides in hormone-receptor binding and smooth muscle contraction, demonstration of specific inhibition of one of the enzymes involved in phosphoinositides breakdown (e.g., phospholipase C) is needed. Lack of contraction would establish the obligatory role of phosphoinositides. No specific inhibitors are available at this time.

The other product in the phosphodiesterase splitting of phosphoinositide is diacylglycerol. In addition to activating protein kinase C, diacylglycerol is converted to phosphatidic acid (an ionophore) or may release arachidonic acid (Fig. 3). The latter can give rise to prostaglandin and eicosanoid biosynthesis as shown in other tissues.[90, 144] Prostaglandins can cause release of calcium from isolated sarcoplasmic reticulum preparations of uterine smooth muscle and inhibit calcium uptake as shown in our laboratory[41, 42, 54, 55] and previously discussed. Thus their action may augment the calcium release initiated by inositol trisphosphate. On the other hand, prostaglandins may actually cause breakdown of phosphoinositides after specific binding to the cell membrane; no data are available on this. Presently we suggest that accelerated synthesis of prostaglandins, stimulated by hormone-receptor binding and increased phosphoinositide metabolism, may further increase intracellular free calcium and lead to uterine contraction and possibly labor.

Regulation of second messengers. Guanine nucleotides are known to be involved in modifying the cAMP system. This occurs through receptors communicating with a pair of guanine nucleotide-binding regulatory proteins (G proteins) in the cell membrane. One of these (G_s) enhances the activity of adenylate cyclase, the enzyme that catalyzes cAMP synthesis, while the other (G_i) inhibits.[145-147] Guanosine 5′-triphosphate (GTP)–liganded adenylate cyclase appears to be the active species, and hydrolysis of GTP to GDP is the primary mechanism of inactivation.[148] Thus GTP is an obligatory cofactor for hormonal stimulation of adenylate cyclase. In vitro some analogs of GTP can substitute for GTP, and in binding studies that use broken cell preparations a stable analog of GTP is desirable. Particulate preparations from the smooth muscle of the rat uterus were shown to specifically bind a GTP analog with a K_D of 1.0 μM.[149]

Although most information about G proteins relates to the adenylate cyclase system, G proteins also appear to be mediators in the inositol trisphosphate system. It is still uncertain what type of G protein is involved. Experiments in various tissues that use permeabilized cells (mast cells) or microsomal preparations (rat liver

or coronary artery) have shown that guanine nucleotide-binding proteins couple receptors with the hydrolysis of phosphoinositides.[150-152] Enhancement by GTP of inositol trisphosphate stimulated calcium release has been demonstrated in rat liver,[153] but not in vascular smooth muscle cells.[154] It has also been suggested that the guanine nucleotide regulatory mechanism may operate independently in mediating calcium release from intracellular stores in nerve cells.[155-157] To date no studies on the uterus have been reported.

Conclusions

Recent evidence has delineated the linking of receptor activation with the production of second messengers. Hormone receptor binding at the cell membrane initiates hydrolysis of phosphoinositides to inositol trisphosphate and diacylglycerol by phospholipase C. This reaction is possibly modified by an as yet unidentified GTP–binding protein. The inositol trisphosphate diffuses to the interior of the cell and releases calcium from the sarcoplasmic reticulum. Diacylglycerol can give rise to prostaglandins, which may release more calcium from the sarcoplasmic reticulum. In the presence of calmodulin, calcium then stimulates the myosin light-chain kinase to phosphorylate myosin; contraction follows. When the calcium level declines, the myosin light-chain kinase becomes inactive. The myosin is dephosphorylated by a phosphatase. Relaxation is furthered by phosphorylation of the myosin light-chain kinase by a cAMP–dependent protein kinase.

CORRESPONDENCE

The detection of facial anomalies with ultrasound

To the Editors:

I feel that the article by Pilu et al. (Prenatal diagnosis of craniofacial malformations with ultrasonography. AM J OBSTET GYNECOL 1986;155:45-50) gives a falsely optimistic view of the sonographic prental diagnosis of craniofacial abnormalities, particularly those involving only the face.

Thirteen of the 14 patients in whom facial abnormalities were diagnosed were associated with major, readily diagnosable cranial malformations. In all of these cases, the cranial findings were of primary importance. Both of the patients in whom there were facial abnormalities not associated with obvious abnormal cranial findings (cases 15 and 16) were missed, although technically adequate examinations of the fetal face were obtained.

The sensitivity and specificity of sonographic examination in the diagnosis of fetal facial malformations remain to be demonstrated. The implication that its accuracy is currently well established is a disservice to both referring physicians and their patients, who may have unrealistic expectations. It also creates a dilemma for the consultant sonologist, who may be expected to deliver accuracy that may not be presently obtainable.

Reply

To the Editors:

In reply to Dr. Koontz's letter, we feel that an important distinction has to be made. In our study (AM J OBSTET GYNECOL 1986;155:45-50), a selected obstetric population at high risk for fetal craniofacial malformation was considered. In each case a detailed and time-consuming ultrasound examination of the fetal face was performed. It is quite obvious that sensitivity and specificity of sonography would be much different in a low-risk obstetric population. With regard to this issue, the interested reader is referred to the very interesting article by Hegge et al.[1] that has been recently published.

Our experience indicates that a targeted examination of the fetal face yields great accuracy in the early prenatal diagnosis of many craniofacial anomalies whether the risk factor is a positive familial history, exposure to teratogens, or an associated fetal anomaly. However, a distinction has to be made. Hypotelorism, hypertelorism, cleft lip, and cleft lip–cleft palate are usually readily identifiable. Some craniofacial malformations, such as micrognathia, can probably be diagnosed only late in gestation, and it is likely that isolated cleft palate is not amenable to prenatal diagnosis. The considerable experience that was collected at Bologna University since our original manuscript was submitted for publication is well correlated with our preliminary data. Although a study with a design similar to ours has not yet appeared in the literature, the increasing number of recent reports dealing with both sophisticated investigation of subtle details of the normal anatomy of fetal facial structures[2] and rather large series of well-documented fetal craniofacial malformations diagnosed before birth[1,3] seem to support our view.

Amniotic fluid trypsin and premature rupture of membranes

To the Editors:

We read the article, "The relationship between amniotic fluid trypsin activity and premature rupture of membranes," (AM J OBSTET GYNECOL 1986;155: 1043-8) by Kanayama et al. with interest and admiration. Nevertheless, we suggest that: (1) the principal conclusion is inaccurately expressed; (2) the case for amniotic fluid trypsin as the principal culprit in premature rupture of membranes remains unproved; and (3) other factors and information should be considered.

The authors write that they demonstrated trypsin activity in amniotic fluid. Rather, they have measured "trypsin-like" enzymatic activity, since the chromogenic substrate used (*N*-benzyl-L-isoleucyl-L-glutamyl-glycyl-L-argenine-p-nitroanilide) demonstrates proteolytic activity by a number of other serine proteases. Interestingly, this same substrate is used to assay coagulation factors II (prothrombin) and X (Stewart-Prower factor).[1,2] A nearly identical synthetic substrate is also used to measure plasminogen activator, plasmin, and urokinase activity.[3,4] Similarly, α_1-antitrypsin is not specific

Table I. Comparative measures of the tensile strength of human amniochorion after 24 hours at 37° C, 6% CO_2 incubation with various enzyme and control solutions; note that trypsin demonstrated the least impairment of membrane strength of enzymes measured

	N	*Mean %*	*SD %*
Buffer control	5	100	±12
Collagenase, 10 μg/ml	5	29	±19
Collagen, 20 μg/ml	5	11	±30
Trypsin, 10 μg/ml	5	92	±15
Trypsin, 20 μg/ml	5	86	±26
Elastase, 20 μg/ml	5	<10	
Pseudomonas aeruginosa (collagenase-producing)	5	<10	

and inhibits a number of trypsin-like proteases.[5] Therefore the effects of other serine proteases and antiproteases were likely also measured in these tests.

One of these enzymes measured was probably plasmin. Burgos et al.[6] and Jenkins et al.[7] demonstrated plasminogen/plasmin in amniochorion and suggested that focal concentrations of this protease participate in the pathogenesis of premature rupture of membranes.

It is likely that the 2-week gestational age difference between the premature rupture of membrane (31 weeks) and control (33 weeks) groups influenced the results. Pocknee and Abramovich[8] demonstrated that amniotic fluid trypsin (determined by radioimmunoassay) decreased rapidly near term. Milwidsky et al.[9] could find no differences in amniotic fluid or fetal membrane acid protease activity among women with or without premature rupture of membranes.

Other information suggest that trypsin is not as important in premature rupture of membranes as hypothesized: (1) Since trypsin-like activity is dispersed in amniotic fluid, it would act to "cover the waterfront" and diffusely weaken amniochorion. Studies performed during the past century do not demonstrate overall weakening of prematurely ruptured membranes.[10] (2) Furthermore, Lavery and Miller[11] noted that meconium exposure decreased strength and elasticity of fetal membranes. They suggested that intrauterine exposure to fetal gastrointestinal enzymes, prominently including trypsin present in meconium, predisposes to premature rupture of membranes. However, meconium staining and premature rupture of membranes could not be correlated in a large clinical review.[11] Previous studies consistently show localized inflammation and/or necrosis adjacent to the rupture site.[12, 13]

Membrane thinning reported here is much more dramatic than that measured by Artal et al.[10] In two earlier studies, Polishuk et al.[14, 15] noted great variability but no consistent evidence of fetal membrane thinning in premature rupture of membranes.

While examining the possibility that ascending, transcervical infection and/or inflammation may focally impair membrane integrity, we[16] have assessed the effects of various bacterial and mammalian proteases on the physical properties of fresh human amniochorion. Although bacterial collagenase (Sigma Chemical Co., St. Louis, Mo.), porcine elastase (Sigma), and collagenase-producing *Pseudomonas aeruginosa* markedly reduced measurements of fetal membrane tensile strength, bovine pancreatic trypsin preparations (Sigma) did not (Table I). Preliminary work shows that human protease–containing neutrophil lysate also reduces membrane strength and elasticity, whereas lymphocyte lysate and other control preparations do not. Sbarra et al.[17] induced similar membrane weakening with direct application of phospholipase A_2 to fetal membranes, which suggests that other enzymatic systems are also involved.

We suggest that highly localized fetal membrane impairment by bacterial-, maternal-, and/or fetal-derived proteases and other substances are probably more important in the pathogenesis of premature rupture of membranes than are trypsin-like substances dispersed in amniotic fluid. Certainly, focal destruction of protease inhibitors could allow damage by a number of proteolytic enzymes.

Reply

To the Editors:

I thank Dr. James A. McGregor and his colleagues for their interest in this report. We also agree with their result that the main cause of premature rupture of membranes is latent chorioamnionitis. Premature rupture of membranes was caused by latent chorioamnionitis in about 60% of the cases in our study. However, chorioamnionitis is not recognized in all fetal membranes with premature rupture of membranes. For example, patients have no pathogenic bacteria or inflamed cells in or around the cervix, no uterine contractions, and their cervixs are closed. Furthermore, the microscopic observations of amniochorion do not contain chorioamnionitis. Even such cases sometimes produce premature rupture of the membranes. What is the mechanism of causation in such cases? We supposed that trypsin in amniotic fluid had proteolytic power according to the circumstances. Trypsin activity in such patients was higher than in controlled groups. We measured trypsin activity with S2222(KabiVitrum Co., Sweden), which is specific for trypsin. As shown in Table I, there is little possibility in measuring thrombin, factor Xa, and plasmin by S2222.

Moreover, we obtained data opposite to theirs, namely, that type III collagen in amnion was degraded by trypsin in amniotic fluid (bovine) and meconium in amniotic fluid (human) (Fig. 1). Thus under what circumstances does trypsin modify its proteolytic activity in amniotic fluid? We recently measured trypsin levels

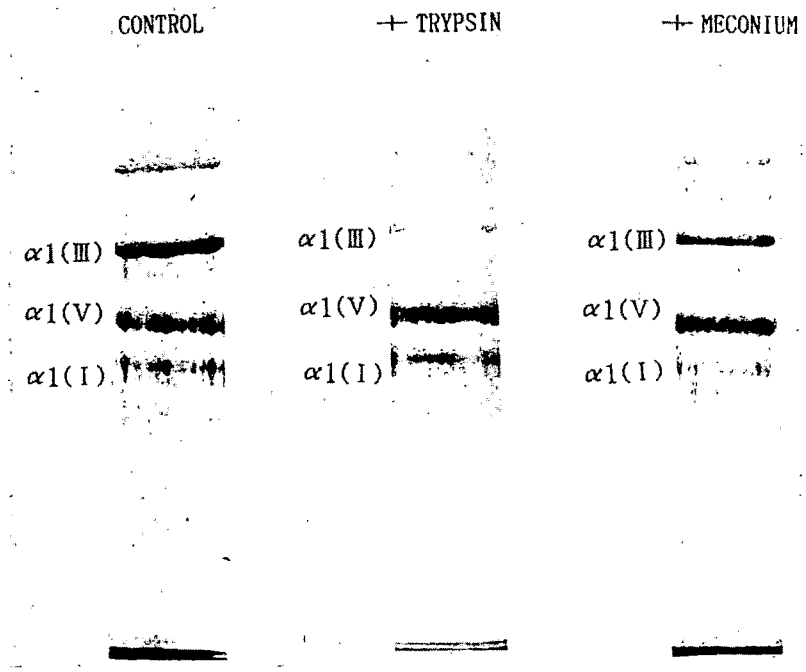

Fig. 1. Electrophoresis (7.5% polyacrylamide gel) of collagen in amnion. (*Left lane* = Normal amniotic collagen; *middle lane* = amniotic collagen (100 mg) treated with trypsin [10 mg] at 35° C for 6 hours; *right lane* = amniotic collagen [100 mg] treated with meconium [10 mg] at 35° C for 6 hours.) The migration of type I, III, and V α-chains is shown. Note the marked reduction of type III collagen in the middle lane and the slight reduction of that in the right lane.

PROM = Premature rupture of membranes.

in amniotic fluid by radioimmunoassay (RIA-gnost Trypsin, Hoechst, West Germany). The results show that there is no difference between premature rupture of membranes and no premature rupture of membranes (Table II), which means that trypsin activity is controlled by the amount of α_1-antitrypsin and not by the amount of trypsin. Our article, which showed low levels of α_1-antitrypsin in cases of premature rupture of membranes, supports this theory.

α_1-Antitrypsin is a serine protease inhibitor that chiefly inhibits neutrophil elastase, chymotrypsin, and trypsin. α_1-Antitrypsin in amniotic fluid mainly comes from maternal blood. α_1-Antitrypsin is transferred from the uterine wall through the amniochorion to the amniotic cavity. Therefore a low value of α_1-antitrypsin in amniotic fluid in cases of premature rupture of membranes suggests that maternal serum has small amount of α_1-antitrypsin or that α_1-antitrypsin is consumed by protease in amniochorion. As a result, the α_1-antitrypsin that reaches the amniotic cavity in such cases does not completely neutralize the trypsin in the amniotic fluid. Secondarily activated trypsin may destroy amniochorion.

In summary, since α_1-antitrypsin is thought to be the main collagenolytic inhibitor in fetal membranes, a decrease of α_1-antitrypsin in fetal membranes helps clarify the cause of premature rupture of membranes.

Possible vascular disruptive origin of hemifacial microsomia?

To the Editors:

In their report on chorionic villus sampling in 1000 cases, Hogge et al. (Chorionic villus sampling: Experience of the first 1000 cases. AM J OBSTET GYNECOL 1986;154:1249-56) mention four congenital anomalies in newborn infants from pregnancies monitored by chorionic villus sampling: Goldenhar syndrome, cloverleaf skull, achondroplasia, and polydactyly. The authors comment that "none of these anomalies appears to be related to the prenatal diagnostic procedure."

I do not quite agree with this statement with respect to the facioauriculovertebral (Goldenhar) complex. This malformation complex is not well defined and might include cases with different genetic and nongenetic etiology. Unfortunately, the authors did not present clinical details of their case. In animal experiments, Poswillo[1,2] induced congenital defects similar to those common in facioauriculovertebral complex by disrupting a fetal neck vessel. It is thought that a hematoma in the fetal neck damaged auricular and mandibular structures and thus finally led to the clinical picture of facioauriculovertebral complex. In a series of monozygotic twins discordant for congenital developmental defects, Schinzel et al.[3] reported an instance of facioauriculovertebral complex in the surviving twin of a fetus papyraceus and concluded that the defect in this instance might have been caused by embolization of thrombotic tissue or necrotic tissue from the deceased twin or its placental section through collaterals in a common placenta into a neck artery of the surviving twin.

In the case of the newborn with facioauriculovertebral complex, it was not mentioned from which area of the chorion the villi were obtained; however, it cannot be excluded that chorionic villus sampling caused a placental hematoma and that clotted blood or necrotic tissue had later embolized via the umbilical cord into a neck artery of the embryo or fetus. Thus facioauriculovertebral complex in a newborn from a pregnancy in which choriocentesis (or amniocentesis through the placenta) had been performed could well have a disruptive vascular origin. To obtain more insight into this possible pathogenesis, pregnancy histories of patients with facioauriculovertebral complex should be obtained with respect to any prenatal invasive diagnostic measures that were undertaken.

Placental bed biopsy technique and vascular lesions

To the Editors:

I have read with interest the review by Robertson et al. (The placental bed biopsy: Review from three European centers. AM J OBSTET GYNECOL 1986;155: 401-12) about their extensive experience with the placental bed biopsy technique in three European centers during the past 30 years.

Vascular lesions of acute atherosis were found regularly in women with preeclampsia and idiopathic intrauterine growth retardation.[1-5] Similar vascular lesions were observed in women with chronic hypertension with or without superimposed preeclampsia,[6] in normotensive women with insulin-dependent diabetes,[6] and in endometrial spiral arteries from first-trimester abortions.[7]

The above mentioned lesions were described mainly in biopsy specimens from the placental bed but not from the parietal decidua. Interestingly, the authors said that "the best material to use to identify acute atherosis is the parietal decidua and not the placental bed or the basal plate of the placenta. The parietal decidua obviously is devoid of trophoblast invasion in spiral

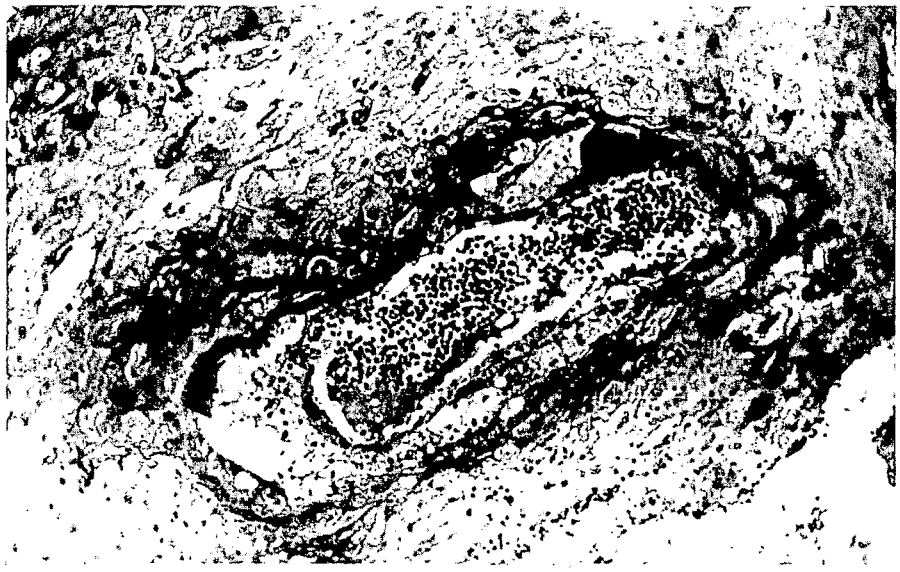

Fig. 1. Spiral artery of the basal plate with acute atherosis from a placenta from an idiopathic small for gestational age infant. (Hematoxylin-eosin stain; magnification ×100.)

Fig. 2. Dense deposits of IgM in two vessels with acute atherosis from a placenta from an infant with idiopathic intrauterine growth retardation. (Immunoperoxidase stain–hematoxylin counterstain; magnification ×100.)

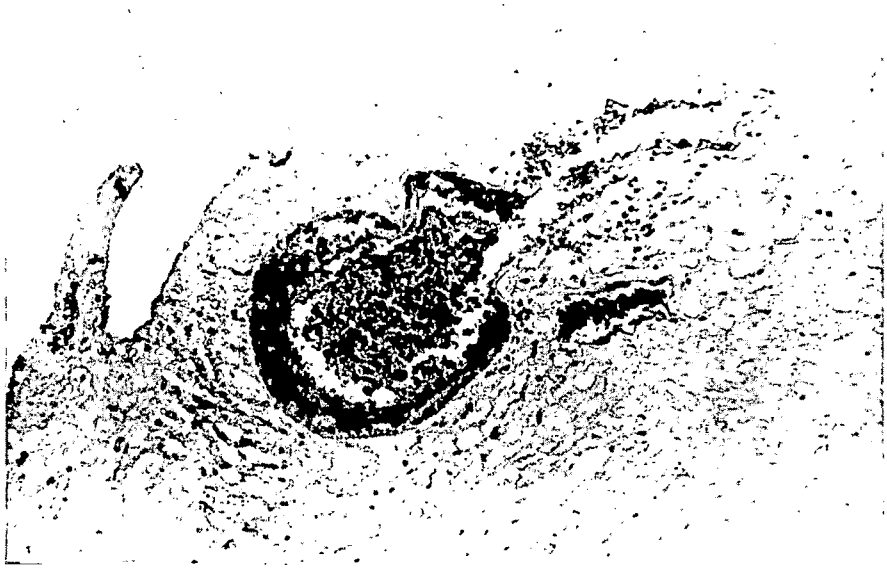

Fig. 3. Spiral artery of parietal decidua with acute atherosis from a placenta from a normotensive, intrauterine growth–retarded infant. Dense granular deposits of IgM are observed within the wall. (Immunoperoxidase stain–hematoxylin counterstain; magnification ×100.)

arteries. This vasculopathy is therefore seen in the parietal decidua in its 'pure' form, uncomplicated by preexisting trophoblast-induced vascular changes. Thus, in studies related mainly with vascular lesions, it is good practice to take biopsy specimens of parietal decidua in addition to those from the placental bed. Rolled-up strips of the placental membranes are a valuable additional source of parietal decidua containing portions of decidual spiral arteries, which may show acute atherosis.

The uteroplacental arteries present difficulties in interpretation with regard to pathologic lesions because their decidual segments have been altered by trophoblast invasion, and it becomes very difficult to differentiate the characteristic fibrinoid material in the vessel wall from the fibrinoid necrosis of an acute vasculopathy. Furthermore degenerated cells in the physiological changes, including trophoblast, accumulate lipid in their cytoplasm."

On the other hand, the authors state that there is little doubt that acute necrotizing lesions in small superficial vessels in the basal decidua but not in the myometrium or parietal decidua can be found in cases of intrauterine growth retardation unassociated with hypertension; their relationship with the acute atherosis characteristic of preeclampsia-eclampsia remains to be determined. However, we have found acute atherosis-like lesions predominantly in parietal decidua and also in the basal plate in placentas from patients with idiopathic intrauterine growth retardation[8, 9] (Fig. 1). These lesions were also seen in those placentas with associated preeclampsia[9] and also in patients with autoimmune diseases.[10]

Interestingly, heavy granular deposits of predominantly IgM (Figs. 2 and 3) and also C3 and Clq were found in lesions of acute atherosis but not in vessels with physiologic changes or an absence of trophoblastic invasion.[11] Furthermore, the frequent feature of leukocyte infiltration surrounding spiral arteries and endometrial glands in the placental bed has been shown to consist mainly of macrophages and T-lymphocytes, suggesting that these findings may be related to a local immune attack during pregnancy.[12] The same may be proposed for vascular lesions of acute atherosis.

Reply

To the Editors:

Although we regard the comments made by Dr. Labarrere on our article as evidence that we have achieved our objective in stimulating discussion and interest in a neglected subject, we do not wish to take issue on the two main points he raises. Our article was intended only as a review of the technology and interpretation of the placental bed biopsy and not as a comprehensive assessment of the pathology of the pregnant uterus in gestational disorders. It may be that his assertion that vasculopathies in the decidua vera are a common feature of intrauterine growth retardation unassociated with hypertensive disorders will prove to be true. In our experience it has not been so, but in such cases we have concentrated our attention on the basal plate of the fetal placenta and the underlying placental bed. However, he is not correct in stating in his brief review of the literature that " the above mentioned lesions were described mainly in biopsies from the placental bed but not from the parietal decidua." Several of our earlier publications illustrate typical acute atherosis in the parietal decidua from cases of hypertensive disorders of pregnancy regardless of whether the cases were also associated with intrauterine growth retardation.

With regard to his proposal that uterine vasculopathies may be the result of an inappropriate immunologic reaction, we purposely did not dwell on this complex and contentious matter, since our review was essentially on morphologic aspects.

Laser excisional conization and laser vaporization for cervical intraepithelial neoplasia

To the Editors:

I was very interested to read the article "A comparison between laser excisional conization and laser vaporization for the treatment of cervical intraepithelial neoplasia" by Baggish (Am J Obstet Gynecol 1986;155:39-44), and I am prompted to make a few comments.

As a pathologist, I echo the sentiment that a serious shortcoming of laser vaporization is the lack of an adequate specimen to allow complete histologic evaluation of the disease. It is my belief that a not inconsiderable number of early invasive lesions are not being diagnosed and are being treated by vaporization.[1] The likelihood of missing a glandular abnormality in a punch biopsy specimen, particularly when cervical intraepithelial neoplasia is also present, is another reason to applaud the suggestion that excision be used as often as possible in place of vaporization.

Although this point of view is expressed in the introduction of the article, it is contradicted in the final paragraph where it is stated that "pure ectocervical lesions . . . may be effectively and easily eradicated by laser vaporization." The foregoing arguments recommend excision for all lesions whether or not the canal is involved.

If this final statement implies that all patients treated by laser excision in this series had lesions passing into the endocervical canal, then I am surprised that an excision 1.5 to 2.0 cm deep is considered adequate. Information from cone biopsies at the Samaritan Hospital, London, most of which were knife cones, shows that the lesion was completely excised in only 66% of those between 1.5 and 2.0 cm deep. I suggest that 2.0 cm is not a deep enough excision in those patients in whom the canal is involved.

I recommend that laser excision conization be considered for those patients whose lesion is purely ectocervical and in whom the canal is not involved. Furthermore, I question the necessity of a preceding biopsy; I believe that if the colposcopic examination is done by an experienced colposcopist who is satisfied that there is no canal extension, no colposcopic or cytologic suspicion of invasive disease, and no glandular abnormality, then it is safe to perform a laser excision conization at an outpatient visit. This saves an additional hospital visit for the patient and in a busy clinic serves to minimize the waiting list time for new patients. The excision in these patients without canal involvement need only be 1.0 to 1.5 cm deep. Since the whole lesion is being removed and subjected to histologic examination, an unsuspected invasive carcinoma or glandular abnormality would be diagnosed at that stage.

Reply

To the Editors:

In response to Dr. Anderson's letter about my article that compared laser excisional cone versus vaporization for the treatment of cervical intraepithelial neoplasia, I will give the following comments: (1) I am pleased that he agrees with the thesis that an excisional cone provides a more adequate specimen for sampling than does a punch biopsy and that by performing a laser excisional cone a greater margin of safety will be provided to those patients with endocervical extension. (2) If one has a "pure" ectocervical lesion, then this may be accurately and safely sampled via biopsies colposcopically directed and treated very adequately by laser vaporization to a depth of 7 mm. Worldwide statistics, including several publications from the United Kingdom,[1] consistently report long-term cure rates of more than 90%. (3) In contrast to a pathologist's viewpoint, as a gynecologist, I am concerned about deep cones that impinge on the internal cervical os and that may be a subsequent factor in infertility and pregnancy loss. A more sensible approach is to assess the depth of the cone by preoperative endocervical endoscopy or by immediate colposcopic examination of the excised and opened specimen. The latter is a technique that we have recently suggested and can demonstrate acetowhite epithelium but of course not abnormal vascular patterns at involved margins. (4) I cannot agree with Dr. Anderson that every patient with cervical intraepithelial neoplasia should have conization biopsy. Although my paper demonstrated that laser conization and vaporization equally share small risks, nevertheless, the cone procedure is more complex, two to three times deeper, and costlier. Similarly, I do not believe it is practical for cone biopsy to substitute for the office punch biopsy performed under colposcopic guidance.

Conjoined twins in triplet pregnancy

To the Editors:

In reference to the interesting case report of Koontz et al. (Antenatal sonographic diagnosis of conjoined twins in a triplet pregnancy. AM J OBSTET GYNECOL 1985;153:230-1), we enclose a figure (Fig. 1) from April 1984 when we encountered a similar case.

In this case, diagnosis was made at 21 weeks' gestation.

The patient, a 36-year-old gravida 5, para 4, insisted on termination of the triplet pregnancy. Medical induction failed and hysterotomy was performed. Unfortunately, the placenta was found to be accreta and therefore hysterectomy was done.

In view of this, it would be more accurate to state that the case of Koontz et al. is the first to be reported and not "the first case . . . diagnosed antenatally with ultrasound."

The Agency for International Development (A.I.D.) has entered into a Cooperative Agreement with Jones Institute for Reproductive Medicine at the Eastern Virginia Medical School (EVMS). This agreement established CONRAD, a program of contraceptive research and development. A core of Jones Institute research scientists will conduct basic applied fertility regulation research at EVMS. Additionally, a large portion of the grant will be distributed to researchers at outside institutions such as universities, research centers, and private companies for the same purpose. As A.I.D. seeks new and improved contraceptive methods that are appropriate for developing country family planning programs, the CONRAD Program is interested in receiving proposals from researchers who can contribute to such technology. An area of particular interest is that of new or improved sterilization techniques, especially those that are nonsurgical and reversible in nature. Other areas include spermicides with viricidal activity and more acceptable and efficacious barrier methods. For more information or to request guidelines for proposals, please contact: Henry L. Gabelnick, Ph.D., Director Extramural Programs and Product Development, The CONRAD Program, 1611 N. Kent St., Suite 806, Arlington, VA 22209. Tel.: (703) 524-4744.

ORTHO-NOVUM 777 Tablets

norethindrone/ethinyl estradiol TRADEMARK

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen.

CONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Oral contraceptive tablets may cause fetal harm when administered to a pregnant woman. Oral contraceptive tablets are contraindicated in women who are pregnant. If the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus (see WARNINGS, No. 5). 8. Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.

The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers. A prospective study conducted in Great Britain estimated that former users have a risk for all cerebrovascular disease 2.6 times greater than that of nonusers. This risk remained elevated for at least six years after last oral contraceptive use. A prospective study conducted in the United States found that past use of oral contraceptives was associated with increased risk of subarachnoid hemorrhage, the relative risk being 5.3. There was also some evidence from this study that the degree of risk may be related to duration of oral contraceptive use. **MYOCARDIAL INFARCTION:** An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. A study suggests that some increased risk of myocardial infarction in oral contraceptive users persists following discontinuation of oral contraceptives and that the degree of the residual risk is related to the duration of the past use. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory disease mortality may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. 4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations and use of oral contraceptives with high hormonal potency and age over 30 years may further increase the woman's risk of hepatocellular adenoma. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. Cases of hepatocellular carcinoma, although rare, have been reported in women taking oral contraceptives. Retrospective studies conducted in the United States and Britain report an increased risk of hepatocellular carcinoma in oral contraceptive users, particularly with increased duration of use. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin, griseofulvin, and tetracycline. **DRUG/LABORATORY TEST INTERACTIONS:** The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Revised 2/87

ORTHO PHARMACEUTICAL CORPORATION
Raritan, N.J. 08869-0602

ORTHO

Beyond low dose...

EXCELLENT RESULTS

Low incidence of nuisance side effects†
Low breakthrough bleeding
Low impact on selected metabolic parameters

21- and 28-day regimens

ORTHO-NOVUM 7/7/7 Tablets

TRADEMARK

norethindrone/ethinyl estradiol

†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.

Please see brief summary of complete Prescribing Information on the preceding page.

on oral contraception:

"The multiphasics contain a low dose of progestin without having an increased incidence of breakthrough bleeding."[3]

"If changes in HDL and HDL_2 levels are to be avoided... the preferred progestin is the estrane norethindrone and not the gonane norgestrel...."[4]

Low BTB with Tri-Norinyl

- Extra midcycle protection that's unique among multiphasics
- Low BTB rates—equivalent to a fixed low-dose OC[2]

Low Impact with Tri-Norinyl

- Minimal lipid and cholesterol impact[4]
- Low incidence of nuisance side effects[2]

TRI-NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

THE LOWEST-DOSE MULTIPHASIC OC WITH NORETHINDRONE

Serious as well as minor side effects have been reported following the use of all oral contraceptives. These include thromboembolic disease. Please see brief summary of prescribing information on next page.

TRI - NORINYL®

(NORETHINDRONE AND ETHINYL ESTRADIOL) TABLETS

TRI-NORINYL® 21-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg)
TRI-NORINYL® 28-Day Tablets (7 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg, 9 green tablets of norethindrone 1.0 mg with ethinyl estradiol 0.035 mg, 5 blue tablets of norethindrone 0.5 mg with ethinyl estradiol 0.035 mg; 7 inert tablets)

ORAL CONTRACEPTIVE (O.C.) AGENTS

Indications Prevention of pregnancy. *DOSE-RELATED RISK OF THROMBOEMBOLISM.* Because studies have shown a positive association between OC estrogen dose and risk of thromboembolism, it is prudent to minimize estrogen exposure. Prescribe an OC with the least amount of estrogen compatible with an acceptable pregnancy rate and patient acceptance. Start new users on OCs containing 0.05 mg or less of estrogen.

Contraindications 1. Known or suspected pregnancy (see Warning #5). 2. Thrombophlebitis or thromboembolic disorders. 3. Past history of deep vein thrombophlebitis or thromboembolic disorders. 4. Undiagnosed abnormal genital bleeding. 5. OCs should not be used by women who have or have had any of the following: a. cerebral vascular or coronary artery disease, including myocardial infarction. b. known or suspected carcinoma of the breast. c. known or suspected estrogen dependent neoplasia. d. benign or malignant liver tumor that developed during use of OCs or other estrogen containing products.

WARNINGS: Cigarette smoking increases the risk of serious cardiovascular side effects from OC use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use OCs should be strongly advised not to smoke.

The use of OCs is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, liver tumor, gall bladder disease, visual disturbances, fetal abnormalities, and hypertension. Practitioners prescribing OCs should be familiar with the following information relating to these risks.

1. *Thromboembolic Disorders and Other Vascular Problems:* An increased risk of thromboembolic and thrombotic disease associated with OC use is established. One study demonstrated an increased relative risk for fatal venous thromboembolism and several studies demonstrated it for non-fatal venous thromboembolism. They estimate that OC users are 4-11 times more likely than nonusers to develop these diseases without evident cause. One British study reported an excess death rate of 40% in OC users, most of which resulted from cardiovascular disease. Another British study showed a lower death rate in OC users than controls; an increase in cardiovascular deaths was seen but was not statistically significant. A U.S. prospective study failed to disclose increased mortality rates from cardiovascular disorders, but a subset analyzed as a retrospective, case-control study showed significant increases in venous thromboembolism. CEREBROVASCULAR DISORDERS. Two American studies demonstrated an increased relative risk for stroke not shown in prior British studies. In an American study of cerebrovascular disorders in women with and without predisposing causes, relative risk of hemorrhagic stroke was estimated as 2.0 times greater and thrombotic stroke as 4-9.5 times greater in users than nonusers. A British long-term follow-up study reported in 1976 a highly significant association between OC use and stroke. Another study had suggested an association in 1974, but the number of cases was too small to estimate the risk. Subarachnoid hemorrhage has been shown to be increased by OC use in British and American studies. Smoking alone increases incidence of these accidents; smoking and pill use appear to increase risk more than either alone.

MYOCARDIAL INFARCTION (MI). Increased relative risk of MI associated with OC use has been reported. One British study found that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia) the higher the risk of developing MI, regardless of OC use. OCs were an additional risk factor. In terms of relative risk, it has been estimated that nonsmoking OC users (smoking is considered a major predisposing condition to MI) are twice as likely to have a fatal MI as nonsmoking nonusers. OC users who are smokers have a 5-fold increased risk of fatal infarction compared to nonsmoking users, and a 10-12-fold increased risk compared to nonsmoking nonusers. The number of cigarettes smoked is important. In determining the importance of these relative risks, baseline rates for various age groups must be considered. (Estimates are based on British vital statistics which show acute MI death rates 2-3 times less than in the U.S. so U.S. death rates could be higher.) Importance of other predisposing conditions in determining relative and absolute risks has not been quantified; other synergistic actions may exist. RISK OF DOSE. Using data from several national adverse reaction reporting systems, British investigators concluded that risk of thromboembolism, including coronary thrombosis, is directly related to estrogen dose in OCs. OCs with 0.1 mg or more of estrogen were associated with a higher risk of thromboembolism than those containing 0.05-0.08 mg but quantity of estrogen may not be the sole factor. This was supported by a U.S. study. A British study found a positive association between dose of progestogen or estrogen and certain thromboembolic conditions. Swedish authorities noted decreased reporting of thromboembolic episodes when higher estrogen preparations were no longer prescribed. Careful epidemiological studies to determine degree of thromboembolic disease risk associated with progestogen-only OCs have not been done. Thromboembolic disease has been reported in women using these products, and they should not be considered free of excess risk. PERSISTENCE OF RISK. Two studies have suggested an increased risk may persist for 6 years after discontinuation of OC use for cerebrovascular disease and 9 years for MI; another study suggested the persistence of risk for subarachnoid hemorrhage. ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES. A large British prospective study estimated mortality rate per 100,000 women per year from circulatory system diseases for OC users and nonusers according to age, smoking habits, and duration of use. The overall annual excess death rate for OC users was estimated to be 20/100,000 (ages 15-34 – 5/100,000; ages 35-44 – 33/100,000; ages 45-49 – 140/100,000). Risk is concentrated in long-term users and in smokers, and may persist after OC discontinuation. Although the study showed a 10-fold increase in death due to circulatory diseases in users for 5 or more years, all occurred in women 35 or older. An update provided the following rates: ages 15-34 – 1/6700 for nonsmokers and 1/2000 for smokers; ages 45 and over – 1/2500 for nonsmokers and 1/500 for smokers. Risk appeared to increase with parity, but not with duration of use. Until more women under 35 with continuous use for 5 or more years are available, it is not possible to assess relative risk for this age group. Data from a variety of sources have been analyzed to estimate the risk of death associated with various methods of contraception. Estimates include combined risk of the contraceptive method (e.g., thromboembolic and thrombotic disease for OCs) plus risk attributable to pregnancy or abortion if the method fails (which varies with the effectiveness of the contraceptive method). The study concluded that mortality associated with all contraceptive methods is below that of childbirth, except for OCs in women over 40 who smoke. (Rates given for pill only/smokers for each age are for smokers as a class. For "heavy" smokers (more than 15 cigarettes a day), the rates would be about double; for "light" smokers (less than 15), about half.) The lowest mortality is with the condom or diaphragm backed up by early abortion. The study also concluded that OC users who smoke, especially over 30, have greater mortality risk than OC users who do not smoke.

Risk of thromboembolic and thrombotic disease associated with OCs increases with age after 30 and for MI is further increased by hypertension, hyperlipidemias, obesity, diabetes, or history of preeclamptic toxemia, and especially by smoking. The following chart gives a gross estimate of risk of death from circulatory disorders associated with OC use.

SMOKING HABITS AND OTHER PREDISPOSING CONDITIONS – RISK ASSOCIATED WITH USE OF OCs

Age	Below 30	30-39	40+
Heavy smokers	C	B	A
Light smokers	D	C	B
Nonsmokers (no predisposing conditions)	D	C,D	C
Nonsmokers (other predisposing conditions)	C	C,B	B,A

A – Use associated with very high risk.
B – Use associated with high risk.
C – Use associated with moderate risk.
D – Use associated with low risk.

Physician and patient should be alert to earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, discontinue OC immediately. A 4-6 fold increased risk of post-surgery thromboembolic complications has been reported in OC users. If feasible, discontinue OCs at least 4 weeks before surgery associated with increased risk of thromboembolism or prolonged immobilization. Before resuming OC after major surgery or bedrest, balance risks of post-surgery thromboembolic complications with contraceptive needs. Data suggest varicose veins substantially increase risk of superficial venous thrombosis of the leg, the risk depending on the severity of the varicosities. 2. *Ocular Lesions:* Neuro-ocular lesions such as optic neuritis or retinal thrombosis have been associated with OC use. Discontinue OC if there is unexplained, sudden, or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions; and institute appropriate diagnostic and therapeutic measures. 3. *Carcinoma:* Long-term continuous administration of natural or synthetic estrogen in certain animals increases certain tumors, benign or malignant, such as breast, cervix, vagina, uterus, ovary, pituitary and liver. Certain synthetic progestogens, none currently in OCs, increase the incidence of mammary nodules, benign and malignant, in dogs. Several retrospective case-control studies reported an increased relative risk (3.1-13.9 times) associating endometrial carcinoma with the prolonged use of estrogens in postmenopausal women. One publication reported the first 30 cases submitted to the registry of cases of adenocarcinoma of the endometrium in women under 40 on OCs. Of the adenocarcinomas found in women without predisposing risk factors for adenocarcinoma of the endometrium (e.g., irregular bleeding when OCs were first given, polycystic ovaries), nearly all occurred in women who had used sequential OCs, which are no longer marketed. No statistical association has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only OCs, although individual cases have been reported. Studies have shown no increased risk of breast cancer to OC or estrogen users. One study found no overall increased risk of breast cancer in OC users but a greater risk was suggested for OC users with documented benign breast disease and for long-term (2-4 years) users. Another study found a history of breast cancer among grandmothers or aunts was significantly more frequent among breast cancer patients who had used an OC continuously for one or more years than among nonusers with breast cancer. One other study indicated an increasing risk of breast cancer in women taking menopausal estrogens, which increased with duration of follow-up. One author suggests that extended (over 6 years) OC use prior to first full term pregnancy was associated with a significant relative risk of breast cancer, and other studies suggested an increased risk of breast cancer with long-term OC use before age 25. A reduced occurrence of benign breast tumors in OC users has been well documented. One study reported malignant melanoma more frequently in OC users than controls and suggests an increased incidence of urinary tract and thyroid cancers. A prospective study of women with cervical dysplasia found an increase in severity and conversion to cancer *in situ* in OC users compared to nonusers. This became statistically significant after 3-4 years of use. Nonreversal of dysplasia within the first 6 months of pill use was suggested to predict progression after prolonged exposure. One study disclosed an increased risk of cancer of the cervix (largely carcinoma *in situ*) in OC users under 40, particularly those who had used OCs over 4 years. Two other studies suggested an increasing incidence of cervical neoplasms with longer duration of OC use. There have been other reports of microglandular hyperplasia of the cervix in OC users. One study reported an association between OC use and endocervical adenocarcinoma. In summary, there is no confirmed evidence from human studies of increased risk of cancer associated with OCs. Close clinical surveillance of all OC users is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, take appropriate diagnostic measures to rule out malignancy. Monitor OC users with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms with particular care. (See also Warnings, 4. *Liver Tumors.*) 4. *Liver Tumors:* Sudden severe abdominal pain or shock may be due to rupture and hemorrhage of a liver tumor. There have been reports associating benign or malignant liver tumors with short-term and long-term OC use. One study reported use of OCs with high hormonal potency and age over 30 may further increase risk of hepatocellular adenoma. Two studies relate risk with duration of use, risk being much greater after 4 or more years of use. Long-term OC users have an estimated annual incidence of hepatocellular adenoma of 3-4/100,000. Although an uncommon lesion, it should be considered in women presenting with an "acute abdomen". The tumor may cause serious or fatal hemorrhage. Patients with liver tumors have demonstrated variable clinical features which may make preoperative diagnosis difficult. Some cases presented because of right upper quadrant masses, while most had signs and symptoms of acute intraperitoneal hemorrhage. Routine radiological and laboratory studies may not be helpful. Liver scans may show a focal defect. Hepatic arteriography may be useful in diagnosing primary liver neoplasm. Cases of hepatocellular carcinoma have been reported in long-term users of OCs.[105-107] An epidemiological study suggested a 4-fold increase in relative risk for hepatocellular carcinoma in OC users for 8 years or more, which increased to 7 in women with markers of hepatitis B. A second study suggested a risk of about 20 for use in excess of 8 years. 5. *Use in or immediately Preceding Pregnancy, Birth Defects in Offspring, and Malignancy in Female Offspring:* Use of female sex hormones – estrogenic and progestational agents – during early pregnancy may seriously damage the offspring. Females exposed *in utero* to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be of the order of 1/1000 exposures or less. Although there is no evidence that OCs further enhance the risk of developing this type of malignancy, such OC users should be monitored with particular care. A high percentage of women exposed to diethylstilbestrol (30-90%) have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether they are a precursor of vaginal malignancy. Male children so exposed may develop urogenital tract abnormalities. Although similar data are not available on other estrogens, it cannot be presumed that they would not induce similar changes. Increased risk of congenital anomalies, including heart and limb defects, has been reported following use of sex hormones, including OCs, in pregnancy. One case-control study estimated a 4.7-fold increased relative risk of limb-reduction defects in infants exposed *in utero* to sex hormones (OCs, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some exposures involved only a few days of treatment. Data suggest risk of limb-reduction defects in exposed fetuses is somewhat less than 1/1000 live births. In a large prospective study, cardiovascular defects in children born to women who received female hormones, including OCs, during early pregnancy occurred at 18.2/1000 births, compared to 7.8/1000 for children not so exposed *in utero.* These results are statistically significant. A Welsh study found a statistically significant excess of neural tube defects among offspring of prior OC users (within 3 months) than among controls. The incidence of twin births may be increased for women who conceive shortly after discontinuing OC use. In the past, female sex hormones were used during pregnancy in an attempt to treat threatened or habitual abortion. There is evidence that estrogens are ineffective, and there is no evidence from well controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing OCs. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping OCs is unknown. If the patient has not adhered to the prescribed schedule, consider possible pregnancy at the first missed period (or 45 days from the last menstrual period if progestogen-only OCs are used) and discontinue OC use until pregnancy has been ruled out. For any patient who has missed two consecutive periods, rule out pregnancy before continuing the OC. If pregnancy is confirmed, tell the patient about potential risks to the fetus and discuss advisability of continuing the pregnancy. Women who discontinue OCs to become pregnant should use an alternate form of contraception for a period of time before attempting to conceive. A 3-month period is supported by a study suggesting increased frequency of neural tube defects in women impregnated during the first 3 months after cessation of OC use. Do not use progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding as a pregnancy test. 6. *Gall Bladder Disease:* Studies report increased risk of gall bladder disease in OC or estrogen users. In one study, an increased risk appeared after 2 years of use and doubled after 4-5 years. In another study, an increased risk was apparent between 6 and 12 months. 7. *Carbohydrate and Lipid Metabolic Effects:* Because a decrease in glucose tolerance has been observed in a significant percentage of patients on OCs, prediabetic and diabetic OC users should be carefully observed. An increase in triglycerides and total phospholipids has been observed in OC users but its clinical significance is unknown. 8. *Elevated Blood Pressure:* An increase in blood pressure has been reported with OC use. Hypertension may occur within a few months of beginning OCs. In the first year of use, incidence of hypertension may be no higher in OC users than in nonusers. Incidence in users increases with exposure and in the fifth year of use is 2.5-3 times that in the first year. Age is strongly correlated with hypertension in OC users. Women with a history of elevated blood pressure (hypertension), preexisting renal disease, history of toxemia or elevated blood pressure during pregnancy, familial tendency to hypertension or its consequences, or history of excessive weight gain or fluid retention during the menstrual cycle may be more likely to develop elevated blood pressure when given OCs and should be monitored closely. Even though elevated blood pressure may remain within the "normal" range, closely watch elevations, particularly for women with other risk factors for cardiovascular disease or stroke. High blood pressure may or may not persist after OC discontinuation. 9. *Headache:* Discontinue OC and evaluate the cause of onset or exacerbation of migraine or development of a new pattern of headache which is recurrent, persistent, or severe. 10. *Bleeding Irregularities:* Breakthrough bleeding, spotting, and missed menses often make users discontinue OCs. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, consider nonfunctional causes. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, use adequate diagnostic measures to rule out pregnancy or malignancy. If pathology has been excluded, time or another formulation may solve the problem. While potentially useful in minimizing menstrual irregularity, change to an OC with a higher estrogen content only if necessary since this may increase the risk of thromboembolic disease. Women with a history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may tend to remain anovulatory or to become amenorrheic after OC discontinuation. Women with these preexisting problems should be advised of this and encouraged to use other contraceptive methods. Post-use anovulation, possibly prolonged, may occur in women without previous irregularities. A higher incidence of galactorrhea and of pituitary tumors (e.g., adenomas) has been associated with amenorrhea in former users compared with nonusers. One study reported a 16-fold increased incidence of pituitary prolactin-secreting tumors among patients with postpill amenorrhea when galactorrhea was present. 11. *Infertility:* There is evidence of impairment of fertility in women discontinuing OCs in comparison with other contraceptive methods, which appears to be independent of duration of use. While impairment diminishes with time, there is an appreciable difference in the results in nulliparous women for OC and other groups 30 months after discontinuation of birth control. For parous women the difference is not apparent 30 months after cessation of contraception. One study suggests that the incidence of *Chlamydia trachomatis* infection, the leading cause of nongonococcal PI.D., is increased by OCs. 12. *Ectopic Pregnancy:* Ectopic as well as intrauterine pregnancy may occur in OC failure. In progestogen-only OC failures, the ratio of ectopic to intrauterine pregnancies is higher than in nonusers, since the drugs are more effective in preventing intrauterine than ectopic pregnancies. 13. *Breast Feeding:* OCs in the postpartum period may interfere with lactation by decreasing quantity and quality of breast milk. A small fraction of OC hormonal agents has been identified in milk of mothers receiving OCs. Effects, if any, on the breast-fed child have not been determined. If feasible, defer OC use until the infant has been weaned. **Precautions** *GENERAL* 1. Take a complete medical and family history before starting OCs. Pretreatment and periodic physical exams should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant lab tests. As a general rule, OCs should not be prescribed for longer than 1 year without another physical. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may enlarge. 3. Observe patients with a history of psychic depression and discontinue OCs if depression recurs to a serious degree. Patients becoming significantly depressed while taking OCs should stop the OC and use an alternate method of contraception to determine whether the symptom is drug related. 4. OCs may cause some fluid retention. Prescribe with caution, and only with careful monitoring, in patients with conditions that might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma or cardiac, hepatic or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence while using OCs. Discontinue OC if jaundice develops. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. OC users may have disturbances in normal tryptophan metabolism that may result in a relative pyridoxine deficiency. The clinical significance is unknown. 8. Serum folate levels may be depressed by OC use. Since the pregnant woman is predisposed to folate deficiency and incidence of folate deficiency increases with increasing gestation, if a woman becomes pregnant shortly after stopping OCs, she may have a greater chance of developing folate deficiency and related complications. 9. Advise the pathologist of OC use when relevant specimens are submitted. 10. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing OCs. For example: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX, and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG, free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. f. Increased phospholipids and triglycerides. g. Temporarily decreased glucose tolerance. 11. Contact lens wearers who develop visual changes or changes in lens tolerance should be assessed by an ophthalmologist and temporary or permanent cessation of wear considered. DRUG INTERACTIONS. OCs may be less effective and there may be increased breakthrough bleeding from interactions with rifampin, isoniazid, ampicillin, tetracycline, neomycin, penicillin V, chloramphenicol, sulfonamides, nitrofurantoin, barbiturates, phenytoin, primidone, analgesics, tranquilizers, antimigraine preparations, antihistamines, and griseofulvin. OCs may alter effectiveness of such other drugs as oral anticoagulants, anticonvulsants, tricyclic antidepressants, antihypertensive agents (e.g., guanethidine), vitamins, hypoglycemic agents, tranquilizers, hypnotic preparations, theophylline, and beta blockers. Toxic liver effects have been reported with a combination of an OC and cyclosporin A. *CARCINOGENESIS* See Warnings. *PREGNANCY* Pregnancy category X. See Contraindications and Warnings. *NURSING MOTHERS* See Warnings. **Adverse Reactions** An increased risk of the following serious adverse reactions has been associated with OC use (see Warnings): thrombophlebitis, thrombosis, pulmonary embolism, coronary thrombosis, cerebral thrombosis, mesenteric thrombosis, liver tumors, cerebral hemorrhage, hypertension, gall bladder disease, congenital anomalies, neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis, Budd-Chiari syndrome, Raynaud's disease, arterial thromboembolism. The following adverse reactions have been reported in OC users and are believed to be drug related: bleeding irregularities (breakthrough bleeding, spotting, missed menses during treatment, amenorrhea after treatment), gastrointestinal symptoms (nausea, vomiting, bloating, abdominal cramps, colitis), dysmenorrhea, infertility after discontinuance of treatment, edema, chloasma or melasma which may persist after drug is discontinued, breast changes (tenderness, enlargement, and secretion), intolerance to contact lenses, changes in corneal curvature (steepening), change in weight (increase or decrease), change in cervical erosion and cervical secretion, possible diminution of lactation when given immediately postpartum, cholestatic jaundice, migraine, increase in size of uterine leiomyomata, rash (allergic), mental depression, reduced tolerance to carbohydrates, vaginal candidiasis, prolactin-secreting pituitary tumors, chiblains. The following adverse reactions have been reported in OC users and the association has been neither confirmed nor refuted: premenstrual-like syndrome, cataracts, changes in libido, chorea, changes in appetite, cystitis-like syndrome, headache, nervousness, dizziness, hirsutism, loss of hair, erythema multiforme, erythema nodosum, hemorrhagic eruptions, vaginitis, porphyria, impaired renal function, malignant nephrosclerosis (hemolytic uremic syndrome), malignant hypertension, acute renal failure, premature supraventricular contractions. **Information for the Patient** (See Patient Package Insert).

A Standard in Progesterone Therapy

Provera® 10 MG TABLETS
(medroxyprogesterone acetate)

WARNING

THE USE OF PROGESTATIONAL AGENTS DURING THE FIRST FOUR MONTHS OF PREGNANCY IS NOT RECOMMENDED.

Progestational agents have been used beginning with the first trimester of pregnancy in an attempt to prevent habitual abortion or treat threatened abortion. There is no adequate evidence that such use is effective and there is evidence of potential harm to the fetus when such drugs are given during the first four months of pregnancy. Furthermore, in the vast majority of women, the cause of abortion is a defective ovum, which progestational agents could not be expected to influence. In addition, the use of progestational agents, with their uterine-relaxant properties, in patients with fertilized defective ova may cause a delay in spontaneous abortion. Therefore, the use of such drugs during the first four months of pregnancy is not recommended.

Several reports suggest an association between intrauterine exposure to female sex hormones and congenital anomalies including congenital heart defects and limb reduction defects. One study estimated a 4.7-fold increased risk of limb reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormone withdrawal tests for pregnancy, or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb reduction defects in exposed fetuses is somewhat less than 1 in 1000.

If the patient is exposed to PROVERA Tablets (medroxyprogesterone acetate) during the first four months of pregnancy or if she becomes pregnant while taking this drug, she should be apprised of the potential risks to the fetus.

INDICATIONS: Secondary amenorrhea; abnormal uterine bleeding due to hormonal imbalance in the absence of organic pathology such as fibroids or uterine cancer.

CONTRAINDICATIONS: Thrombophlebitis, thromboembolic disorders, cerebral apoplexy or patients with a past history of these conditions. Liver dysfunction or disease. Known or suspected malignancy of breast or genital organs. Undiagnosed vaginal bleeding. Missed abortion. Known sensitivity to medroxyprogesterone acetate. As a diagnostic test to pregnancy.

WARNINGS: 1. Immediately discontinue administration should any of the following thrombotic disorders occur or be suspected: thrombophlebitis, cerebrovascular disorders, pulmonary embolism, retinal thrombosis. **2.** Beagle dogs treated with medroxyprogesterone acetate developed mammary nodules some of which were malignant. Although nodules occasionally appeared in control animals, they were intermittent in nature; whereas the nodules in the drug treated animals were larger, more numerous, persistent, and there were some breast malignancies with metastases. Their significance with respect to humans has not been established. **3.** Discontinue medication pending examination if there is sudden partial or complete loss of vision, onset of proptosis, diplopia, or migraine. If papilledema or retinal vascular lesions occur, withdraw medication. **4.** Detectable amounts of progestin have been identified in the milk of mothers receiving the drug. The effect of this on the nursing infant has not been determined. **5.** Usage in pregnancy is not recommended (see Warning box). **6.** Three major studies in Great Britain and one in this country have shown a statistically significant association between thrombophlebitis, pulmonary embolism, cerebral thrombosis and embolism and the use of oral contraceptives. It has been estimated that users are several times as likely to undergo thromboembolic disease without evident cause as nonusers. The American study indicated that the risk did not persist after discontinuation, and it was not enhanced by long-continued administration.

PRECAUTIONS: A pretreatment physical exam should include special reference to breast and pelvic organs and a Papanicolaou smear. This drug may cause fluid retention; therefore, carefully observe patients with conditions influenced by fluid retention such as epilepsy, migraine, asthma, and cardiac or renal dysfunction. In irregular bleeding per vaginum, bear in mind nonfunctional causes and perform adequate diagnostic measures. Advise pathologist of therapy when submitting relevant specimens. Carefully observe patients with history of psychic depression and discontinue drug if serious depression recurs. Any possible influence of prolonged therapy on pituitary, ovarian, adrenal, hepatic, or uterine function awaits further study. Decreased glucose tolerance has been observed in a small percentage of patients on estrogen-progestin combinations; therefore, carefully observe diabetic patients receiving progestin therapy. Age constitutes no absolute limiting factor, although onset of climacteric may be masked. Because of the occasional occurrence of thrombotic disorders (thrombophlebitis, pulmonary embolism, retinal thrombosis, and cerebrovascular disorders) in patients taking estrogen-progestin combinations and since the mechanism is obscure, the physician should be alert to the earliest manifestation of these disorders. (See Patient Information for complete prescribing information.)

ADVERSE REACTIONS: Pregnancy: (see Warning box); **Breast:** rare reports of breast tenderness or galactorrhea; **Skin:** sensitivity reactions including pruritus, urticaria, edema and generalized rash; acne, alopecia and hirsutism in a few patients; **Thromboembolic Phenomena** including thrombophlebitis and pulmonary embolism.

The following adverse reactions have been observed in women taking progestins including medroxyprogesterone acetate: breakthrough bleeding; spotting; change in menstrual flow; amenorrhea; edema; change in weight; changes in cervical erosion and secretions; cholestatic jaundice; rash (allergic) with and without pruritus; mental depression; anaphylaxis and anaphylactoid reactions; pyrexia; insomnia; nausea and somnolence.

A statistically significant association has been demonstrated between use of estrogen-progestin combination drugs and the serious adverse reactions of thrombophlebitis, pulmonary embolism and cerebral thrombosis and embolism. Therefore, patients on progestin therapy should be carefully observed.

Although available evidence is suggestive, a relationship has been neither confirmed nor refuted for the association of the serious adverse reaction of neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis.

The following adverse reactions have been observed in patients receiving estrogen-progestin combination drugs: rise in blood pressure in susceptible individuals; premenstrual-like syndrome; changes in libido; changes in appetite; cystitis-like syndrome; headache; nervousness; dizziness; fatigue; backache; hirsutism; loss of scalp hair; erythema multiforme; erythema nodosum; hemorrhagic eruption; and itching.Therefore, observe patients on progestin therapy carefully.

The following laboratory results may be altered by the use of estrogen-progestin combination drugs: increased sulfobromophthalein retention and other hepatic function tests; coagulation tests (increase in prothrombin factors VII, VIII, IX and X); metyrapone test; pregnanediol determination; thyroid function tests (increase in PBI, and butanol extractable protein bound iodine and decrease in T^3 uptake values).

Caution: Federal law prohibits dispensing without prescription.

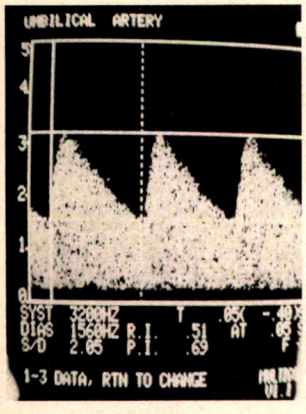
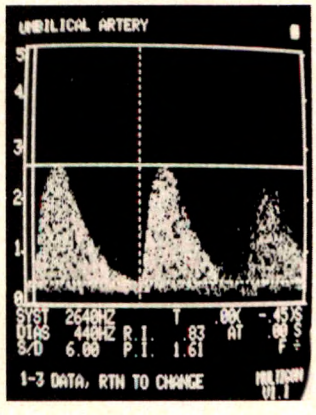
500A™ UMBILICAL-UTERINE ARTERY DOPPLER SPECTRUM ANALYZER

LETS YOU EVALUATE

UTEROPLACENTAL PERFUSION BY SPECTRUM ANALYSIS OF UMBILICAL AND MATERNAL UTERINE ARTERY DOPPLER WAVEFORMS



CLINICAL RESULTS[1-8] SHOW THAT YOU CAN:



- DETECT *IUGR* FROM 20 WEEKS IN SINGLETON PREGNANCIES AND 30 WEEKS IN TWIN PREGNANCIES
- USE UTERINE ARTERY WAVEFORMS IN THE MANAGEMENT OF MATERNAL PREECLAMPSIA
- USE UMBILICAL ARTERY VELOCITY WAVEFORMS IN THE MANAGEMENT OF DIABETIC PREGNANCIES

Umbilical and uterine artery waveforms are easily obtained from early pregnancy on. Low power continuous wave Doppler spectrum analysis is used in a simple test to measure the peripheral resistance in the placental circulation. This resistance is measured by taking the ratio of the systolic to diastolic (S/D) velocity. The S/D ratio is compared to established normal values to determine the presence of abnormal resistance.

The Model 500A™ automatically computes the systolic to diastolic ratio as well as resistance and pulsatility indices.

Normal Umbilical Waveform
S/D = 2.05

Abnormal Umbilical Waveform
S/D = 6.00

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Authorization to photocopy items for internal or personal use, or the internal or personal use of specific clients, is granted by The C. V. Mosby Company for libraries and other users registered with the Copyright Clearance Center (CCC) Transactional Reporting Service, provided that 10¢ per page is paid directly to CCC, 29 Congress St., Salem, MA 01970; phone (617)744-3350. disposable applicator

SYNTEX

SYNTEX LABORATORIES, INC.
PALO ALTO, CA 94304

BRIEF SUMMARY

INDICATIONS: FEMSTAT® (butoconazole nitrate) vaginal cream 2.0% is indicated for local treatment of vulvovaginal mycotic infections caused by Candida species. Confirm the diagnosis by KOH smears and/or cultures. FEMSTAT can be used with oral contraceptives and antibiotics. It is effective in non-pregnant women and during the second and third trimesters of pregnancy.

CONTRAINDICATIONS: FEMSTAT is contraindicated in patients hypersensitive to any of the ingredients.

PRECAUTIONS: General: If clinical symptoms persist, repeat microbiological tests to rule out other pathogens and confirm the diagnosis. Discontinue drug if sensitization or irritation occurs.

Information for the Patient: Do not discontinue prematurely during menstruation or because of symptomatic relief.

Carcinogenesis: Animal studies have not been done.

Mutagenesis: Mutagenicity studies were negative.

Impairment of Fertility: Animal studies showed no impairment of fertility.

Pregnancy Category C: Adverse effects were noted in animals treated with high oral doses. No studies were done in women during first trimester. Patients in the second or third trimester have shown no adverse effects attributable to the drug.

Nursing Mothers: Use with caution.

Pediatric Use: Safety and efficacy have not been established.

ADVERSE REACTIONS: Vulvar/vaginal burning in 2.3% of patients, vulvar itching in 0.9%, discharge, soreness, swelling, itching of fingers each in 0.2%. Complaints caused 1.6% to discontinue drug.

DOSAGE AND ADMINISTRATION: Non-pregnant Patients: The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for three days. Treatment can be extended for an additional three days if necessary.

Pregnant Patients (second and third trimesters only): The recommended dose is one applicatorful of cream (approximately 5 grams) intravaginally at bedtime for six days.

CAUTION:
Federal law prohibits dispensing without prescription.

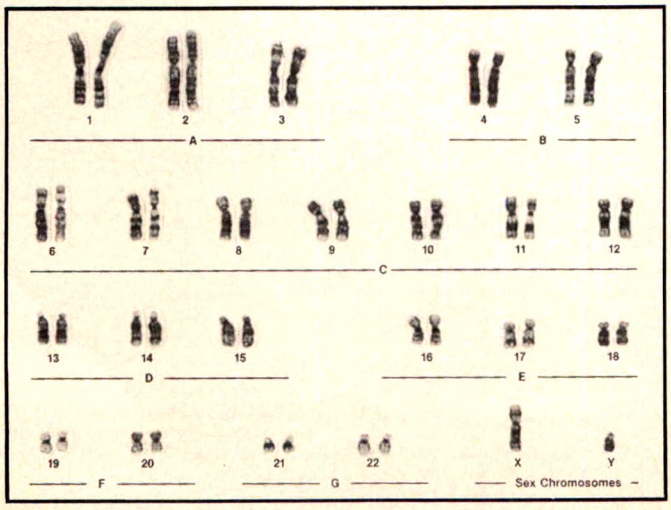
When you need genetic testing results . . .

S SERVICE

Vivigen operates a full service genetic testing laboratory, offering chromosome analysis on amniocentesis, blood, and bone marrow specimens, as well as AFP and Tay-Sachs carrier screening tests. Full service means prepaid overnight shipping of specimens in Vivigen packing kits, fast turn-around time, thorough and accurate analysis, and individual consultation with physicians at any time.

T TECHNOLOGY

The medical staff at Vivigen is well qualified and experienced in the field of genetics. Kathleen E. Richkind, Ph.D., Laboratory Director, Stirling M. Puck, M.D., Director of Medical Genetics, and Kirk A. Aleck, M.D., Director of Biochemical Genetics, are all Board certified by the American Board of Medical Genetics. They are supported by a highly trained staff, who are licensed in their respective areas of technical competence.



A ACCURACY

Physicians at major university medical centers, HMOs, and in private practice all choose Vivigen for its reliability and accurate results. The laboratory is approved by the College of American Pathologists, licensed by CLIA and the state of New York, and voluntarily participates in quality control programs run by CAP, New York, the Foundation for Blood Research, and the International Tay-Sachs Testing Quality Control Panel.

T TURN-AROUND

Amniocentesis and the long wait for results (two to four weeks for most laboratories) cause tremendous anxiety among patients and their families. Vivigen's turn-around time averages only seven days, shortening this waiting period dramatically and providing an extra margin of safety should further testing or action be required. Physicians in nineteen states across the country rely on Vivigen for genetic testing.

TURN-AROUND: 7 Days for Amniocentesis Specimens

We have opportunities for physicians who love their work.

At Maxicare, we not only care for our members, we care about them.

So, when some of them asked us to add medical centers to the Maxicare system, we did just that.

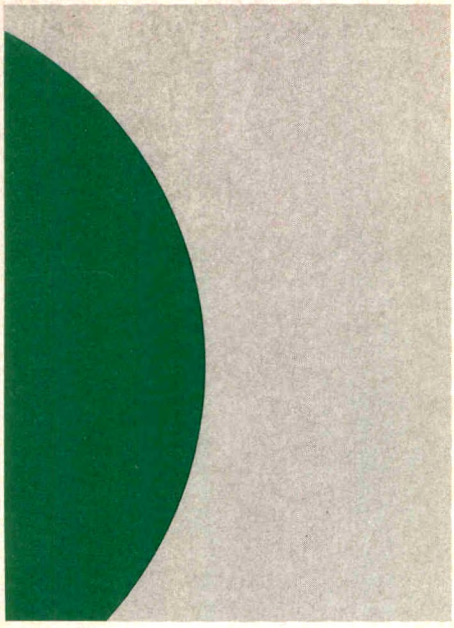
Which is why we're looking for dedicated physicians in OB/GYN.

Maxicare is a national organization. In fact, we're the largest publicly-held HMO in the country.

So we can offer generous salaries, vacations, and retirement plans.

Not to mention paid malpractice insurance. Continuing medical education opportunities and area training programs. And the opportunity to work with the very latest technology.

There are a lot of big reasons for a physician to become a part of the Maxicare program.



But we're especially interested in doctors who think the little reasons are equally important.

Contact Physician Placement, (213)568-9000.

THE SECOND INTERNATIONAL BEIJING SYMPOSIUM ON OBSTETRICS AND PERINATAL MEDICINE

THE SECOND INTERNATIONAL BEIJING TRADE EXHIBITION ON OBSTETRICS AND PERINATAL MEDICINE

THE GREAT WALL SHERATON HOTEL BEIJING, CHINA, APRIL 22 – 24, 1988

The "Second International Beijing Symposium on Obstetrics and Perinatal Medicine" will take place in Beijing from April 22 – 24, 1988.

Current topics in obstetrics and perinatal medicine will be discussed with internationally renowned specialists during the event.

The scientific sessions will provide an appropriate forum for the exchange of experience, expertise, and news of the most recent advances in obstetrics and perinatal medicine.

An in-depth discussion of current and future trends in obstetrics and perinatal medicine will follow.

CHAIRMEN:
PROFESSOR YAN REN-YIN, M.D.
PROFESSOR J.W. DUDENHAUSEN, M.D.

JOINT ORGANIZERS:
THE BEIJING MEDICAL UNIVERSITY
AND
THE INTERNATIONAL QUINTESSENCE PUBLISHING GROUP

REGISTRATION FEE: $ 280

THE SECOND INTERNATIONAL BEIJING SYMPOSIUM ON OBSTETRICS AND PERINATAL MEDICINE

Transvaginal sonography (TVS) is an emerging diagnostic tool for introducing new information beyond the capabilities of transabdominal scanning. The international faculty are leaders in TVS who will unfold the exciting horizons of this new approach. Besides explaining the basic physics involved, the presentations will show how practical clinical information from usage of TVS translates into new standards for care. Significant improvements for in-vitro fertilization, embryo transfer, and tubal pregnancy diagnosis will be highlighted. The role of this new diagnostic technique in the clinician's office will be presented and debated. Interaction between faculty and participants will be sparked during the panel sessions and case presentations.

INFORMATION FOR AUTHORS

Editorial policies

The requirements for manuscripts submitted to the *American Journal of Obstetrics and Gynecology* conform to the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals" established by the International Committee of Medical Journal Editors and published in *Annals of Internal Medicine* 1982;96(6):766-71. Certain requirements unique to our JOURNAL are provided in Information for Authors, published in each issue of the JOURNAL, and in more detail in the *Guide to Writing for the American Journal of Obstetrics and Gynecology*. The latter may be obtained from The C. V. Mosby Company or the Editors on request.

Manuscripts should be submitted to one of the three Editors as follows: (1) Dr. Brewer—all articles originating from the southeastern quadrant of the United States or Canada and those presented before one of the official sponsoring societies, except the Society for Gynecologic Investigation and The Society of Perinatal Obstetricians; (2) Dr. Zuspan—articles from the northeastern quadrant of the United States, Japan, Israel, Italy, and England, articles written for Clinical Opinion and Current Development, and Letters to the Editors; (3) Dr. Quilligan—articles from the north central states (including Ohio), states west of the Mississippi, Hawaii, Alaska, and abroad (except Japan, Israel, Italy, and England). Dr. Quilligan is responsible for articles from the Society for Gynecologic Investigation. Manuscripts should be submitted to Dr. Roger A. Lobo, Women's Hospital, 1240 North Mission Road, Room 1M2, Los Angeles, CA 90033. Dr. Zuspan is responsible for articles from The Society of Perinatal Obstetricians. Manuscripts should be submitted to Dr. John A. Read, 9102 Lake Steilacoom Point Road, S.W., Tacoma, WA 98498.

Most of the provisions of the Copyright Act of 1976 became effective on January 1, 1978. **Therefore, all manuscripts must be accompanied by the following written statement, signed by one author:** "The undersigned author transfers all copyright ownership of the manuscript [title of article] to The C. V. Mosby Company in the event the work is published. The undersigned author warrants that the article is original, is not under consideration by another journal, and has not been previously published. I sign for and accept responsibility for releasing this material on behalf of any and all co-authors." Authors will be consulted, when possible, regarding republication of their material.

When submitting a manuscript, an author should include, if applicable, a full statement about all submissions and prior reports in any medium that might be regarded as prior or duplicate publication of the same or similar work. Copies of such material should be included with the submitted manuscript. Articles previously published in another language will not be considered.

It is assumed by the Editors that articles emanating from a particular institution are submitted with the approval of the requisite authority. Articles dealing with human experimentation that require local institutional approval must have this approval prior to submission of the article for publication and it should be so indicated in the Methods section. Reports of experiments on animals must indicate which guidelines for the care and use of the animals were followed.

Statements and opinions expressed in articles and communications herein are those of the author(s) and not necessarily those of the Editor(s) or Publisher and the Edi-

tor(s) and Publisher disclaim any responsibility or liability for such material. Neither the Editor(s) nor the Publisher guarantees, warrants, or endorses any product or service advertised in this publication, nor do they guarantee any claim made by the manufacturer of such product or service.

General requirements for preparation of manuscripts

The original and two good-quality copies of the manuscript and three glossy prints of illustrations are required.

Manuscripts must be typed double spaced on one side only on 22 by 28 cm (8 1/2 by 11 inch) white bond paper with 1 inch margins at top, bottom, and sides. Number pages consecutively in the upper right-hand corner in the following order: title page, abstract, body of text, references, legends, and tables.

Title page. The title page should contain in sequence the title (concise and suitable for indexing purposes); author line with first name, middle initial, and last name of all authors and their highest academic degree (both M.D. and Ph.D. are acceptable); city(ies), state(s) in which the study was conducted; divisional, or departmental, and institutional affiliations at the time the study was performed; acknowledgement of source(s) of support; presented line, if applicable; disclaimers, if any; name and address of author to whom requests for reprints should be addressed (if reprints will not be available, it should be so stated); and name and address of author responsible for correspondence concerning the manuscript if different from author to whom reprint requests are addressed. At the bottom of the title page supply a short title for the running head not exceeding 52 characters (including word spaces).

Abstract page and key words/phrases. On manuscript page two is the abstract, also typed double spaced with the required margins and headed by the title of the article and author(s) name(s). Abstracts for regular articles, Current Investigation, Clinical Opinion, and Current Development may not exceed 150 words. Abstracts for case reports and brief communications may not exceed 50 words. Below the abstract list 3 to 5 *key words* or short phrases for indexing purposes.

Text. Do not hesitate to write your manuscript in the first-person, active voice if it is more appropriate to the information you wish to convey. The passive voice is generally more effective for describing techniques or observations since the emphasis is on the "action" rather than the person performing the action.

Only standard abbreviations are to be used. Consult the *Council of Biology Editors Style Manual* or the AMA's *Manual for Authors and Editors.* Abbreviations in the title are not acceptable. They should be avoided, if possible, in the abstract. In the text they should be kept to a practical minimum. The full term for which an abbreviation stands should precede its first use in the text unless it is a standard unit of measurement.

Either the generic, chemical, or proprietary names of drugs may be used. If the generic or chemical name is used, authors may, if they desire, insert the proprietary name in parentheses after the first mention in the text, with the name of the manufacturer and city and state.

Regular articles are customarily organized into the following sections: an introduction and headings that identify Material and Methods, Results, and Comment. Authors may wish to summarize their findings in a short paragraph at the end of the Comment section. This format may not be appropriate for some types of articles.

In the introduction, state concisely the purpose and rationale for the study and cite only the most pertinent references as background.

In the *Material and Methods section* describe briefly (but in sufficient detail to permit other workers to evaluate and reproduce the results) the plan, patients and/or experimental animals and controls, methods and procedures utilized, and statistical method(s) employed.

In the *Results section* present the detailed findings. Include mentions of all tables and/or figures. Avoid duplication of text and supporting material. Emphasize only your important observations; do not compare your observations to those of others. Such comparisons and comments are reserved for the Comment section.

In the *Comment section* state the importance and significance of your findings but do not repeat the details given in the Results section. Limit your opinions to those strictly indicated by the facts in your report. Compare your findings with those of others. No new data should be presented in this section.

Acknowledgments. Acknowledge only persons who have made substantive contributions to the study.

References. A reasonable number, except for case reports and brief communications, limited to 2, and Current Development, for which there is no limit. Number references consecutively in the order in which they are mentioned in the text. Use the format of the "Uniform Requirements for Manuscripts Submitted to Biomedical Journals." Journal titles should conform to abbreviations used in *Cumulated Index Medicus.*

Illustrations and tables. A reasonable number of halftone and line illustrations will be reproduced without charge, but special arrangements must be made with the Editors for color reproduction. For color photographs, submit original transparencies and two sets of unmounted prints on glossy paper with good color balance. For black and white illustrations, submit three sets of 3 by 4 inch (minimum) to 5 by 7 inch (maximum) unmounted glossy photographic prints. Figures must be cited consecutively in the text in Arabic numerals and identified thusly on the back of the print (gummed label with author(s) name(s), title of article, number, and top marked clearly). Do not use paper clips. Legends must accompany all figures; type double spaced on a single sheet of paper if possible and number with manuscript in sequence after the references. Titles should be included in the legend, *not* on the print.

All lettering must be done with commercially available paste-on letters (or numbers) or by a professional; typed or freehand lettering is not acceptable. All lettering must be in proportion to the drawing, graph, or photograph. Original drawings, appropriately done in black India ink, roentgenograms, and other material must be submitted as glossy photographic prints with good black and white contrast. Consistency in size within the article is strongly preferred. Any special instructions regarding sizing should be clearly noted. Illustrations will be returned only on the author's request.

Tables should be typed on separate sheets of paper and

Estimating length of manuscript

The length of text material (introduction through Comment section) in regular manuscripts accepted for publication normally ranges from 750 to 4200 words (an average of 2000 words). A 4200 word text can seldom be accepted, especially if tables and figures are included. The average manuscript of 2000 words of text with abstract, 3 tables with captions, 2 figures with legends, and references makes a 5.7 page article in the JOURNAL. The 2000 words of text alone make approximately 8 pages of manuscript typed double spaced with the required 1 inch margins (approximately 250 words per page). A table or figure that occupies both columns of half a JOURNAL page is equivalent to approximately 500 typed words in manuscript. Thus if a greater number of illustrations and tables are used, the length of the text should be adjusted accordingly.

included at the end of the text, one to a page. They should be numbered in Roman numerals. Each table must be cited in sequence at an appropriate point in the text. Captions should be brief yet indicate clearly the purpose or content of each table and each column precisely defined by headings. Abbreviations and special designations should be explained in a footnote to the table. Special arrangements must be made with the Editors for elaborate tables because of space limitations.

Illustrations and tables should supplement, not duplicate, the text; presentation in either one or the other will suffice.

Permissions and photographic consent. Previously published tables and figures must be correctly referenced and written permission from the copyright holder included with the manuscript. Photographs of identifiable persons must be accompanied by signed releases or else all recognizable features masked.

Requirements for special sections

Case reports and brief clinical and basic science communications. Limit of 700 words, 2 references. Include abstract of 50 words maximum, 3 to 5 key words/phrases for indexing purposes, and short title. If tables and/or figures are used, an equivalent number of words must be deducted from the total (see "Estimating Length of Manuscript").

Current Investigation. Same requirements as for a regular article.

Clinical Opinion. Limit of 3000 words, 16 references. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Current Development. Limit of 6000 words. Include abstract of 50 to 150 words, 3 to 5 key words/phrases, and short title. Submit to Dr. Zuspan.

Correspondence. Two types of correspondence will be considered for publication. (1) A Letter to the Editors commenting on an article that has appeared in the JOURNAL should be brief and directly related to the published article. The editorial staff reserves the right to shorten letters if necessary and to make minor editorial alterations without reference to the writer. Letters may be published together with a reply from the original author. As space for letters is limited, only a selection of letters submitted may be published. (2) A brief case presentation or a short report of a pertinent observation in the form of a Letter to the Editors will be considered for publication. All letters should be typed double spaced. Letters should be sent to Dr. Zuspan.

Announcements. Announcements of major meetings and other significant activities must be received at least 8 weeks before the desired month of publication. All announcements carry a charge of $60.00 U.S. and the fee must accompany the request to publish. Information will be limited to title of meeting, date, place, and an address to obtain further information. Send announcements and payment, payable to this JOURNAL, to Kay G. Goehler, Senior Manuscript Editor, Journal Editing, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146.

Books. Books received will be listed in the JOURNAL. They should be sent to Dr. Gerbie. No books will be returned.

Reprints. Reprints of articles must be obtained from the author. The corresponding author will receive a price schedule and order form at the time of publication. Reprints in quantities must be ordered from the Publisher with the author's consent.

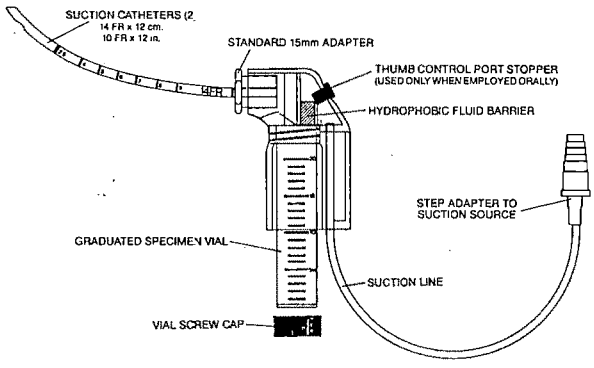
Business communications. Communications of a business nature and all advertising communications should be addressed to: Journal Publisher, The C. V. Mosby Company, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, or call Journal Advertising Production Manager (314) 872-8370.

Checklist

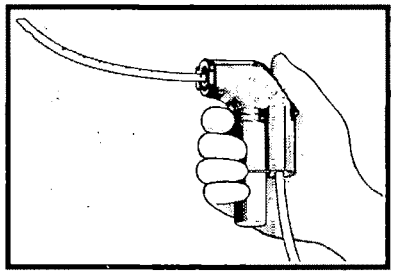
—Letter of submission
—Copyright transfer letter
—Original and two xerographic copies of manuscript
—Title page
  —Title of article
  —Full name(s) and affiliations of author(s)
  —Author to whom correspondence is to be sent
  —Reprint request line or line stating reprints not available
  —Short title
—Abstract (double spaced), 3 to 5 key words/phrases
—Article proper (double spaced)
—References (double spaced), on a separate sheet
—Legends (double spaced), on a separate sheet
—Tables (double spaced), each on a separate sheet
—Illustrations, properly labeled (three copies of glossy prints)
—Permission to reproduce published material

GESCO®

MADE IN U.S.A.



GESCO ASPIRATOR™



WITH REMOVABLE TRAP PAT PEND

FOR SUCTIONING AND SAMPLING MUCOUS/MECONIUM

ADVANTAGES & FEATURES

1. Can be held and operated with one hand.
2. Is designed for use with mechanical or wall type suction, but may also be used orally, as required.
3. The amount of suction can be accurately varied by means of a conveniently located thumb control port.
4. Is fitted with an easily removable fluid trap, with screw cap provided, ideal for collecting samples as needed for testing.
5. Is baffled internally to direct all aspirants into fluid trap and fitted with a vapor barrier reducing clinician exposure to possible contaminants.
6. The Standard (E.T. Tube) 15mm. Catheter Adaptor (HUB) allows for utilization of different types, sizes and lengths of catheters.
7. When patient is hypoxic, is easily adapted to provide intermittent ventilation with standard equipment.
8. Permits clinician to use catheters separately when involved in delicate intubations.
9. Is of a configuration affording a clear, unobstructed view during intubation or suctioning procedure.
10. Is fitted with universal type tubing connector for simple adaptation to standard hospital vacuum systems.

COST EFFECTIVE: Eliminates Traps, Bulb Syringes, Catheters and other accessory equipment normally associated with the suctioning procedure!

SAFETY ORIENTED: Supports Infection Control by reducing Clinician, Environment and Equipment exposure to possibly infected body fluids, contaminated by such as AIDS, Chlamydia, Gonorrhea, Hepatitis, Herpes and Syphilis.

MEFOXIN® (Cefoxitin Sodium, MSD) is indicated for the treatment of intraabdominal, gynecological, lower respiratory tract, and skin and skin-structure infections due to designated susceptible organisms including members of the *Bacteroides fragilis* group. (See Brief Summary for complete listing of Indications.)

MEFOXIN is contraindicated in patients who have shown hypersensitivity to cefoxitin and the cephalosporin group of antibiotics. Before therapy with MEFOXIN is instituted, careful inquiry should be made to determine whether the patient has had previous hypersensitivity reactions to cefoxitin, cephalosporins, penicillins, or other drugs. This product should be given with caution to penicillin-sensitive patients.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use.

fter year after year after year a

- ☐ Extensive hospital experience in 11 million patients

the facts favor Mefoxin® IV/IM

(Cefoxitin Sodium | MSD)

For a Brief Summary of Prescribing Information, please see following page.

MSD
MERCK SHARP & DOHME

Mefoxin® IV/IM (Cefoxitin Sodium | MSD)

Indications and Usage: *Treatment*—Serious infections caused by susceptible strains of the designated microorganisms in the following diseases:

LOWER RESPIRATORY TRACT INFECTIONS, including pneumonia and lung abscess, caused by *Streptococcus pneumoniae* (formerly *Diplococcus pneumoniae*), other streptococci (excluding enterococci, e.g., *Strep. faecalis*), *Staphylococcus aureus* (penicillinase and non-penicillinase producing), *Escherichia coli*, *Klebsiella* species, *Hemophilus influenzae*, and *Bacteroides* species.

GENITOURINARY INFECTIONS. Urinary tract infections caused by *E. coli*, *Klebsiella* species, *Proteus mirabilis*, indole-positive *Proteus* (i.e., *P. morganii*, *P. rettgeri*, and *P. vulgaris*), and *Providencia* species. Uncomplicated gonorrhea due to *Neisseria gonorrhoeae* (penicillinase and non-penicillinase producing).

INTRA-ABDOMINAL INFECTIONS, including peritonitis and intra-abdominal abscess, caused by *E. coli*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ and *Clostridium* species.

GYNECOLOGICAL INFECTIONS, including endometritis, pelvic cellulitis, and pelvic inflammatory disease, caused by *E. coli*, *N. gonorrhoeae* (penicillinase and non-penicillinase producing), *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, *Peptostreptococcus* species, and group B streptococci.

SEPTICEMIA caused by *Strep. pneumoniae* (formerly *D. pneumoniae*), *Staph. aureus* (penicillinase and non-penicillinase producing), *E. coli*, *Klebsiella* species, and *Bacteroides* species including the *B. fragilis* group.§

BONE AND JOINT INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing).

SKIN AND SKIN STRUCTURE INFECTIONS caused by *Staph. aureus* (penicillinase and non-penicillinase producing), *Staph. epidermidis*, streptococci (excluding enterococci, e.g., *Strep. faecalis*), *E. coli*, *P. mirabilis*, *Klebsiella* species, *Bacteroides* species including the *B. fragilis* group,§ *Clostridium* species, *Peptococcus* species, and *Peptostreptococcus* species.

Although appropriate culture and susceptibility studies should be performed, therapy may be started while awaiting these results. Cefoxitin is not active *in vitro* against most strains of *Pseudomonas aeruginosa* and enterococci (e.g., *Strep. faecalis*) and many strains of *Enterobacter cloacae*. Methicillin-resistant staphylococci are almost uniformly resistant to cefoxitin.

Contraindications: Previous hypersensitivity to cefoxitin and the cephalosporin group of antibiotics.

Warnings: BEFORE THERAPY IS INSTITUTED, CAREFUL INQUIRY SHOULD BE MADE TO DETERMINE PREVIOUS HYPERSENSITIVITY REACTIONS TO CEFOXITIN, CEPHALOSPORINS, PENICILLINS, OR OTHER DRUGS. GIVE WITH CAUTION TO PENICILLIN-SENSITIVE PATIENTS. ANTIBIOTICS SHOULD BE ADMINISTERED WITH CAUTION TO ANY PATIENT WHO HAS DEMONSTRATED SOME FORM OF ALLERGY, PARTICULARLY TO DRUGS. IF AN ALLERGIC REACTION TO CEFOXITIN OCCURS, DISCONTINUE THE DRUG. SERIOUS HYPERSENSITIVITY REACTIONS MAY REQUIRE EPINEPHRINE AND OTHER EMERGENCY MEASURES.

Pseudomembranous colitis, from mild to life-threatening in severity, has been reported with virtually all antibiotics (including cephalosporins); therefore, it is important to consider its diagnosis when diarrhea develops in association with antibiotic use. Broad-spectrum antibiotics alter normal flora of colon and may permit overgrowth of clostridia; a toxin produced by *Clostridium difficile* is a primary cause of antibiotic-associated colitis. Mild cases may respond to drug discontinuance alone; in more severe cases, management may include sigmoidoscopy, appropriate bacteriological studies, fluid, electrolyte and protein supplementation, and use of a drug such as oral vancomycin; isolation of the patient may be advisable. Other causes of colitis should also be considered.

Precautions: *General*—Total daily dose should be reduced in patients with reduced urinary output due to renal insufficiency because high and prolonged serum antibiotic concentrations can occur from usual doses. Prescribe with caution in patients with a history of gastrointestinal disease, particularly colitis. Prolonged use may result in overgrowth of nonsusceptible organisms; repeated evaluation of the patient's condition is essential. If superinfection occurs, take appropriate measures.

Drug Interactions—Increased nephrotoxicity has been reported following concomitant administration of cephalosporins and aminoglycoside antibiotics.

Drug/Laboratory Test Interactions—High concentrations (>100 mcg/mL) may interfere with measurement of serum and urine creatinine levels by the Jaffé reaction and produce false increases of modest degree in creatinine levels reported; serum samples should not be analyzed for creatinine if withdrawn within 2 hours of cefoxitin administration. High concentrations may interfere with measurement of urinary 17-hydroxy-corticosteroids by the Porter-Silber reaction and produce false increases of modest degree in levels reported. A false-positive reaction for glucose in urine has been observed with CLINITEST ‖ reagent tablets.

Carcinogenesis, Mutagenesis, Fertility Impairment—No long-term animal study has been performed on carcinogenic or mutagenic potential. Rat studies at approximately three times maximum recommended human dosage revealed no effects on fertility or mating ability.

Pregnancy Category B—Reproduction studies in rats and mice did not reveal teratogenic or fetal toxic effects, although fetal weights were slightly decreased. In rabbits, cefoxitin was associated with a high incidence of abortion and maternal death, neither considered teratogenic. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers—Excreted in human milk: Exercise caution.

Pediatric Use—Safety and efficacy in infants from birth to three months have not yet been established. In children three months and older, higher doses have been associated with increased incidence of eosinophilia and elevated SGOT.

Adverse Reactions: The most common adverse reactions have been local reactions following intravenous or intramuscular injection. Other adverse reactions have been encountered infrequently. *Local Reactions*—Thrombophlebitis with intravenous administration; pain, induration, and tenderness after intramuscular injections. *Allergic Reactions*—Rash (including exfoliative dermatitis), pruritus, eosinophilia, fever, and other allergic reactions including anaphylaxis. *Cardiovascular*—Hypotension. *Gastrointestinal*—Diarrhea, including documented pseudomembranous colitis during or after treatment, and, rarely, nausea and vomiting. *Blood*—Eosinophilia, leukopenia including granulocytopenia, neutropenia, anemia, including hemolytic anemia, thrombocytopenia, and bone marrow depression. A positive direct Coombs test may develop in some individuals, especially those with azotemia. *Liver Function*—Transient elevations in SGOT, SGPT, serum LDH, and serum alkaline phosphatase. *Renal Function*—Elevations in serum creatinine and/or blood urea nitrogen levels and, rarely, acute renal failure.

Note: In group A beta-hemolytic streptococcal infections, therapy should be maintained for at least 10 days to guard against the risk of rheumatic fever or glomerulonephritis. In staphylococcal and other infections involving a collection of pus, surgical drainage should be carried out where indicated. Intramuscular injections should be well within the body of a relatively large muscle such as the upper outer quadrant of the buttock (i.e., gluteus maximus); aspiration is necessary to avoid inadvertent injection into a blood vessel. The total daily dosage in infants and children should not exceed 12 grams.

How Supplied: Sterile cefoxitin sodium in vials, infusion bottles, and ADD-Vantage®# vials containing 1 gram or 2 grams cefoxitin equivalent and in 10-gram bulk bottles.

§ *B. fragilis*, *B. distasonis*, *B. ovatus*, *B. thetaiotaomicron*, *B. vulgatus*

The Editors and The C. V. Mosby Company take this opportunity to acknowledge those reviewers who have contributed many hours and much effort in the evaluation of manuscripts submitted to the JOURNAL during the past year. Without their interest and help, publication of the JOURNAL would be very difficult indeed. We also continue to seek advice from reviewers and readers alike as regards their overall evaluation of the JOURNAL.

In vitro conversion of pregnenolone to progesterone in human term placenta and fetal membranes before and after onset of labor

Firyal S. Khan-Dawood, Ph.D.
Chicago, Illinois

To determine the role of placental progesterone in the onset of labor, tissue progesterone concentrations and in vitro conversion of tritiated pregnenolone to progesterone were examined in the placentas, chorion, and amnion of 12 term pregnancies delivered by cesarean section with or without labor and vaginal delivery. In all instances, the placenta had significantly higher progesterone concentrations than the chorion or amnion. Progesterone concentrations in the chorion were significantly lower after the onset of labor than before. The placenta and chorion but not the amnion converted pregnenolone to progesterone; the placenta had a significantly greater conversion rate than the chorion in all instances. Placental conversion of pregnenolone to progesterone increased significantly after labor to reach a maximum with vaginal delivery. Chorionic conversion of pregnenolone to progesterone was significantly increased after vaginal delivery but was similar after cesarean section with or without labor. The reduced tissue progesterone in the chorion, together with enhanced placental and chorionic production of progesterone from its precursor, pregnenolone, suggest that rapid metabolism and increased binding of progesterone locally in the placenta and membranes may lead to the local withdrawal or decline of progesterone and onset of labor. (AM J OBSTET GYNECOL 1987;157:1333-7.)

Key words: Progesterone, pregnenolone, placenta, fetal membranes, labor

Although a decline in circulating progesterone has been found in some species at the approach of the onset of labor,[1-3] such a clear change has yet to be convincingly demonstrated in human labor. Because the placenta is the major source of progesterone in late human pregnancy, progesterone production and local concentrations in the placenta and membranes and their direct contact with the uterus may be more relevant to the onset of uterine activity in women. Thus a change toward either reduced placental production or increased placental metabolism of progesterone at the approach of or during labor could provide for a local withdrawal of progesterone with accompanying reduction of the threshold of uterine muscle excitability. Since such local changes in placental progesterone metabolism could potentially modulate uterine activity, studies of the placental progesterone-synthesizing reserve capacity might provide useful information toward a better understanding of the contribution of progesterone in the onset of labor.

One approach would be to examine the in vitro bioconversion of pregnenolone to progesterone, which reflects the enzyme complex 5-ene-3B-hydroxysteroid dehydrogenase and 5-ene-4-ene isomerase but specifically the placental steroidogenic enzyme 5-ene-3B-hydroxysteroid dehydrogenase. Therefore this study was carried out to determine the tissue concentrations of progesterone and the conversion rates of pregnenolone to progesterone in placental and fetal membrane tissues before and after the onset of human labor and parturition.

Material and methods

Patients. Placentas and membranes were obtained from 12 women with uncomplicated term (38 to 40 weeks) pregnancy. Six women had spontaneous normal labor and vaginal delivery, three had spontaneous labor but underwent cesarean section for breech or other malpresentation, large fetus, or previous cesarean section after they were in established first stage of labor, and three had elective cesarean section.

Tissue collection and preparation. Twelve placentas with membranes attached were collected immediately at the time of delivery. Each placenta was immediately

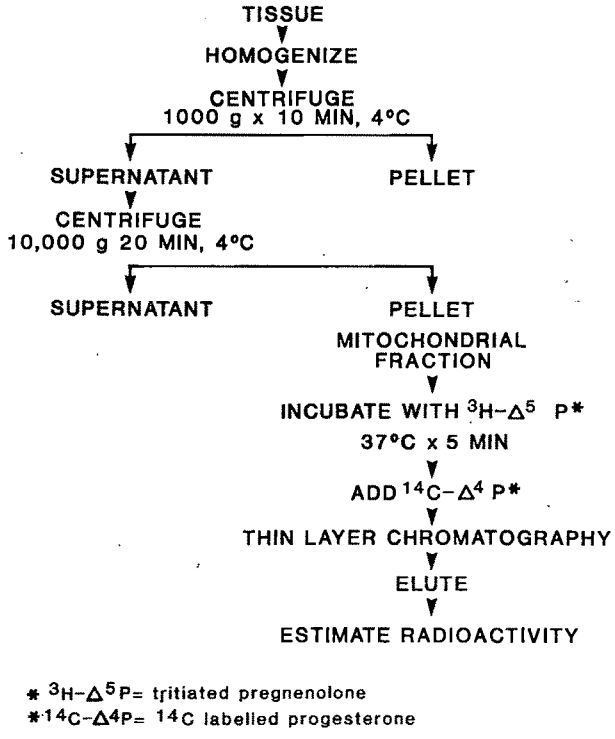

Fig. 1. Schematic outline of the steps for obtaining mitochondrial preparation from placental tissue, chorion, or amnion for use in determining the in vitro bioconversion of pregnenolone to progesterone.

placed in crushed ice in the operating room and rapidly transported to the laboratory. All manipulations were carried out at 4° C. Each placenta was dissected and samples (2 gm each) of cotyledons, chorion, and amnion were removed separately and washed in ice-cold 0.9% sodium chloride solution to remove blood. Each washed tissue specimen was either homogenized immediately or dried over filter papers and kept frozen at −70° C until ready for analysis. The method for homogenizing the tissue and obtaining mitochondrial preparation is outlined in Fig. 1. Samples of the final tissue preparation were verified by electron microscopy to be mitochondria. The cytosol fraction was used for determining intracellular concentration of progesterone.

Pregnenolone to progesterone conversion. In vitro bioconversion of pregnenolone to progesterone by placental cotyledon, amnion, and chorion was determined with the mitochondrial preparation of the respective tissues as previously described by us[4] in detail. The optimal experimental conditions for the study were determined for amnion and chorion and found to be similar for the placental cotyledon.[4] Each determination was performed in duplicate. The radioactive steroids, [7-^{3}H(N)]pregnenolone and [4-^{14}C]progesterone were purchased from New England Nuclear (Boston, Mass.) and had a purity of greater than 99%. They were checked further for purity by thin layer chromatography and high-pressure liquid chromatography. The mitochondrial content for each assay tube was 2.5 to 3.5 mg/protein/ml, and 0.05 μCi of [7-^{3}H(N)]pregnenolone (specific activity, 19.3 Ci/mmol) was added. The substrate concentration used was arrived at by titrating increasing concentrations of tritiated pregnenolone with a constant amount (2.5 to 3.5 mg) of mitochondrial preparation. The concentration of tritiated pregnenolone, which gave the maximum conversion to progesterone, was then used for all assays. Incubation was carried out in a shaking water bath at 37° C for 30 minutes. The reaction was terminated by placing the tubes in an ice bath, and 0.03 μmol each of unlabeled progesterone and pregnenolone, and about 10,000 cpm of [4-^{14}C]progesterone (specific activity, 57.2 mCi/mmol) were added. After mixing and allowing equilibration for 5 minutes, the mixture was extracted twice with diethyl ether:acetyl acetate (1:1, by volume). The combined organic extract was dried and subjected to thin layer chromatography on silica gel plates with chloroform:acetone:ethanol (84:15:1, by volume). Unlabeled progesterone and pregnenolone served as reference standards. Progesterone appeared as a dark absorbed spot under wavelength ultraviolet light and its R_f, relative to the solvent front, was 0.51. Pregnenolone, which appeared as a bluish red spot after spraying with 10% alcoholic phosphomolybdic acid and heated for 1 minute at 100° C, had an R_f, relative to the solvent front, of 0.38. The spots corresponding to progesterone and pregnenolone were cut out, put into scintillation vials to each of which 8 ml of scintillation fluid was added, and then counted for tritium-labeled and carbon 14–labeled standards. Equivalent amounts of tritiated pregnenolone and carbon 14–progesterone as originally used were counted for their radioactivity. The enzymatic activity was calculated from the conversion of tritiated pregnenolone to tritiated progesterone, which was corrected for the methodologic losses and subtraction of the blank. The recovery of [4-^{14}C]progesterone was 88% to 92% when incubated with inactivated mitochondria obtained by boiling the mitochondrial fractions. In preliminary experiments, the purity of the isolated progesterone formed was established by reverse isotope dilution. Blanks were determined from experimental tubes containing the solutions used for the reactions but without adding any tissue fractions and the substrate tritiated pregnenolone. At the end of the incubation period, the mixture was subjected to thin layer chromatography, and the spot corresponding to progesterone was eluted and counted for tritium-labeled radioactivity. This was used as the blank to subtract from the radioactivity corresponding to progesterone in the tubes containing

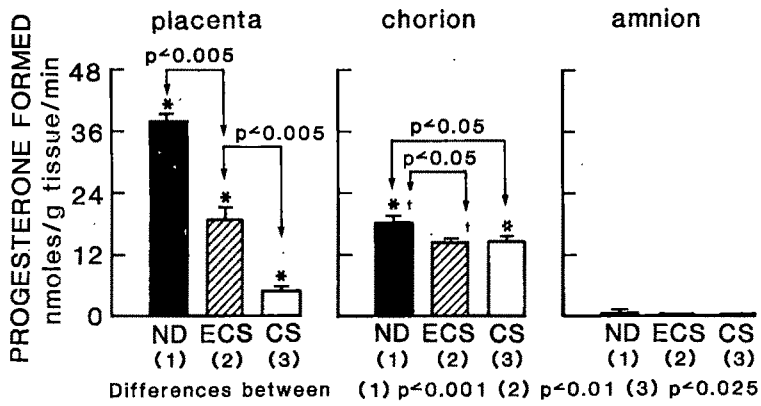

Fig. 2. Mean ± SEM of the in vitro conversion rate of pregnenolone to progesterone in placental tissue, chorion, and amnion from patients with spontaneous normal labor (n = 6) and delivery and from patients undergoing cesarean section after established labor (n = 3) or cesarean section without labor (n = 3). (*ND* = Normal delivery; *ECS* = cesarean section after onset of labor; *CS* = elective cesarean section without labor.)

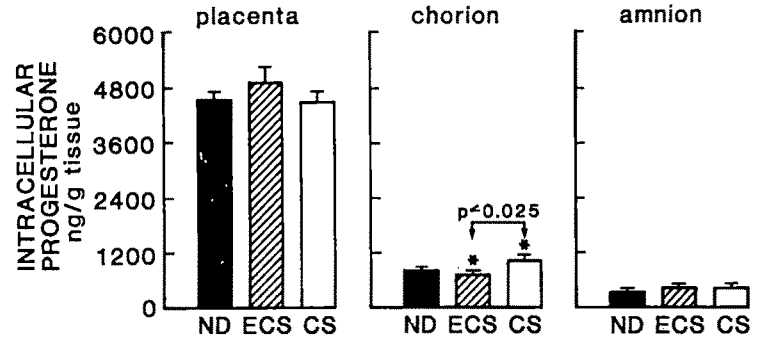

Fig. 3. Intracellular (cytosol) concentrations of progesterone (mean ± SEM) in placental tissue, chorion, and amnion from patients with normal labor and delivery (n = 6) and from patients undergoing cesarean section without labor (n = 3) or cesarean section without labor (n = 3). (*ND* = Normal delivery; *ECS* = cesarean section after onset of labor; *CS* = elective cesarean section without labor.)

tissue mitochondria. The blanks were consistently less than 1% of the substrate used in the experiment tubes. All results were corrected for blanks.

Protein content for the mitochondrial preparation was determined by the method of Lowry et al.[5] with bovine serum albumin as the standard.

Cytosol progesterone. Intracellular progesterone concentrations were determined in the cytosol fraction by a sensitive and specific radioimmunoassay[6] using progesterone antiserum raised in rabbits immunized against progesterone-11–oxime bovine serum albumin conjugate. All results were corrected for procedural losses.

Statistical/analysis. All comparisons of means ± SEM of conversion rates of pregnenolone to progesterone in similar tissues between different groups of patients were analyzed by means of the nonpaired Student *t* test. Differences between different tissues of the same group of patients were analyzed by the paired Student *t* test.

Results

Fig. 2 shows that the rate of pregnenolone to progesterone in placentas from normal delivery (38.7 ± 1.3 nmol/min/gm of tissue) was significantly higher than in cesarean section after labor (19.1 ± 0.50 nmol/min/gm of tissue) or elective cesarean section without labor (5.1 ± 1.8 nmol/min/gm of tissue) (p = <0.005). Similarly, the chorion biosynthesized more progesterone from pregnenolone in normal delivery (19.7 ± 1.1 nmol/min/gm of tissue) than in cesarean section after labor (14.1 ± 1.2 nmol/min/gm of tissue) or cesarean section without labor 14.7 ± 0.4 nmol/min/gm of tissue) (p = <0.05). The amnion had little or undetectable conversion of pregnenolone to progesterone in all three clinical types of delivery situations. The placenta

was significantly faster than the chorion or amnion in the bioconversion of pregnenolone to progesterone in patients with normal delivery ($p = <0.001$).

Progesterone concentrations in the cytosol of placental tissue, chorion, and amnion are shown in Fig. 3. The mean ± SEM progesterone concentration in the placenta was 4590 ± 137 ng/gm of tissue after normal delivery, 4465 ± 336 ng/gm of tissue after cesarean section with labor, and 4496 ± 228 ng/gm of tissue after cesarean section without labor. The corresponding progesterone concentrations in the chorion were 897 ± 25, 813 ± 26, and 933 ± 21 ng/gm of tissue; in the amnion they were 399 ± 16, 453 ± 35, and 448 ± 19 ng/gm of tissue. In all subjects, cytosol progesterone concentrations were significantly higher in the placenta than in the chorion or amnion ($p = <0.001$).

Comment

The importance of progesterone as a key regulator in the endocrine and biochemical cascade leading to uterine activation and parturition has been strongly supported by Csapo.[7] In the present study, an attempt was made to examine the role of local progesterone content and its biosynthesis reserve capacity within the placenta and its membranes during spontaneous labor. It is clear that there are significantly higher concentrations of progesterone within the placental cotyledon than within either the chorion or the amnion on a weight-for-weight basis. The placenta has about five times higher progesterone concentration than the chorion and about 10 to 12 times higher than the amnion. With the actual placental cotyledon, there is no apparent significant changes when labor ensued. However, in the chorion, there is significantly less tissue progesterone when labor begins with no futher change, irrespective of the second stage of labor. This suggests that locally there is a fall in the concentration of progesterone within the chorionic membrane tissue immediately before or with the onset of labor. A fall in local progesterone within the chorion can lead to labilization of the lysosomes with release of phospholipase A_2, which causes generation of arachidonic acid and prostaglandin biosynthesis. The chorion has been shown to have a high capacity for prostaglandin synthesis and is thought to be the major source of prostaglandins found in the amniotic fluid.[8] An alternative effect of the falling progesterone concentration in the chorion is to generate the precursor fatty acid, arachidonic acid, which is shuttled to the decidua to be transformed into prostaglandins.[9]

In vitro bioconversion of pregnenolone to progesterone indicates that in placental cotyledon, the rate of progesterone formation is significantly enhanced with the onset of spontaneous labor and further increased after the second stage of labor and vaginal delivery. This suggests that a labor-associated mechanism or factor activates the enzyme complex 5-ene-3β-hydroxysteroid dehydrogenase and 5-ene-4-ene isomerase. This may initially appear paradoxic with respect to progesterone withdrawal and onset of labor. However pregnenolone-progesterone conversion gives a measure of the tissue enzyme activity and capacity for progesterone biosynthesis from its precursor, pregnenolone. Furthermore, the placental tissue concentrations of progesterone do not show any significant difference with or without labor. Although the enzymes for pregnenolone-progesterone conversion may be activated with labor, other factors such as reduced precursor availability, local in vitro factors inhibiting progesterone formation, or increased progesterone metabolism may account for the absence of changes in tissue progesterone. Progesterone levels in the uterine vein draining from the placenta have been found to decline significantly with labor, thus indirectly suggesting reduced placental progesterone output.[7]

Several studies, including those from our laboratory,[4, 9-11] have indicated that steroids such as estrone, estradiol, estriol, testosterone, dehydroepiandrosterone sulfate, and progesterone can inhibit local placental progesterone biosynthesis. Steroids such as estradiol and estriol, as well as the C_{19} androgens, are produced in the trophoblast cells of the placenta during aromatization of precursor steroids transferred from the fetus. During pregnancy, placental production and secretion of estradiol and estriol increase until term and therefore could possibly exert retroinhibition of the enzyme 5-ene-3B-hydroxysteroid dehydrogenase that leads to reduced placental production of progesterone in vivo. However, when the inhibiting steroids are removed such as in the in vitro experiments in the present study, the ability of the placental cotyledon to produce progesterone is not inhibited.

Our findings indicate that the amnion converts hardly any pregnenolone to progesterone but the chorion does. The chorion obtained after the second stage of labor (delivery) converts significantly more pregnenolone to progesterone than chorion obtained after elective cesarean section or cesarean section during the first stage of labor. After the onset of labor, tissue progesterone concentrations are reduced, but no further change occurs after the second stage of labor. This suggests that the progesterone produced is locally metabolized or converted within the tissues, since progesterone levels in the uterine vein[7] decline with labor. Although the placental tissue has increasing 20-hydroxysteroid oxidoreductase enzyme activity and therefore increasing rates of progesterone metabolism with advancing gestation,[12] the fetal membranes decrease their rates of progesterone metabolism at term.[13]

Within the fetal membranes, progesterone-binding substance[14] binds progesterone and thus reduces progesterone concentration of free tissue. A fall in progesterone levels may cause labilization of lysosomes and release of the lysosomal enzyme, phospholipase A_2, leading to initiation of the arachidonic acid casade and prostaglandin production.

The present findings indicate labor-related reduction in progesterone production from pregnenolone in the placenta and chorion but decreased progesterone concentration in the chorionic tissue with the onset of labor, suggesting possibly the binding of progesterone to the progesterone-binding substance in the fetal membranes[14] and therefore not measurable. If the metabolism of progesterone and the activity of progesterone-binding substance in the fetal membranes and placenta are taken into consideration, the present findings indicate that progesterone production from its precursor does not appear to be impeded. However, progesterone is taken up for binding with the progesterone-binding substance in the fetal membranes while the placenta can rapidly metabolize progesterone to reduce its availability and drainage out of the uterus. Such a series of mechanisms affecting local progesterone production, binding, and metabolism within the immediate environment of the placenta, fetal membranes, and uterus is consistent with and lend support to the concept that local withdrawal of progesterone plays an important role in the onset of human labor.

Metabolism of lipoproteins by human fetal hepatocytes

Bruce R. Carr, M.D.
Dallas, Texas

The rate of clearance of lipoproteins from plasma appears to play a role in the development of atherogenesis. The liver may account for as much as two thirds of the removal of low-density lipoprotein and one third of the clearance of high-density lipoprotein in certain animal species and humans, mainly by receptor-mediated pathways. The purpose of the present investigation was to determine if human fetal hepatocytes maintained in vitro take up and degrade lipoproteins. We first determined that the maximal binding capacity of iodine 125–iodo-LDL was approximately 300 ng of low-density lipoprotein protein/mg of membrane protein and an apparent dissociation constant of approximately 60 μg low-density lipoprotein protein/ml in membranes prepared from human fetal liver. We found that the maximal uptake of [^{125}I]iodo-LDL and [^{125}I]iodo-HDL by fetal hepatocytes occurred after 12 hours of incubation. Low-density lipoprotein uptake preceded the appearance of degradation products by 4 hours, and thereafter the degradation of low-density lipoprotein increased linearly for at least 24 hours. In contrast, high-density lipoprotein was not degraded to any extent by fetal hepatocytes. [^{125}I]Iodo-LDL uptake and degradation were inhibited more than 75% by preincubation with low-density lipoprotein but not significantly by high-density lipoprotein, whereas [^{125}I]iodo-HDL uptake was inhibited 70% by preincubation with high-density lipoprotein but not by low-density lipoprotein. In summary, human fetal hepatocytes take up and degrade low-density lipoprotein by a receptor-mediated process similar to that described for human extrahepatic tissues. (Am J Obstet Gynecol 1987;157:1338-44.)

Key words: Low-density lipoprotein, high-density lipoprotein, liver, human, fetal

The clearance of lipoprotein cholesterol from plasma appears to play a role in the development of atherogenesis in humans. Circulating low-density lipoproteins are removed from plasma by a combination of receptor-dependent and receptor-independent mechanisms by various tissues in many animal species.[1] Most investigators have reported that the receptor-dependent mechanisms of low-density lipoproteins account for 56% to 80% of the low-density lipoprotein turnover in various animal species[1, 2] and humans.[3] Although the adrenal gland is the organ in which the rate of low-density lipoprotein catabolism is the greatest on a tissue weight basis, the liver, by virtue of its size, is the major site of low-density lipoprotein catabolism in rats, swine, rabbits, and also humans.[2] The mechanism of uptake and metabolism of high-density lipoproteins is less well understood, but the adrenal, gonads, and liver are believed to be the principal sites of clearance of high-density lipoproteins.[4]

Very little information is available on the metabolism of lipoproteins by human liver cells. In a preliminary study Brown et al.[5] reported that human fetal liver membrane preparations demonstrated saturable binding for low-density lipoproteins. The affinity and maximal binding were less than that observed in human fetal adrenal glands and testes. Hoeg et al.[6] recently reported that the affinity for low-density lipoproteins was less in human adult livers compared with fibroblasts. The purpose of the present investigation was to determine if human fetal hepatocytes maintained in vitro would take up and degrade lipoproteins and to determine if the mechanisms were similar to that observed for extrahepatic human tissues.

Material and methods

Liver tissue. Liver tissue was obtained from abortuses of 10-24 weeks' gestation delivered by induced abortion (dilatation and extraction). Tissues were obtained in accordance with the Donors Anatomical Gift Act of the State of Texas after written consent was obtained from the woman to be aborted. A consent form and protocol approved by the Institutional Review Board of the University of Texas Health Science Center at Dallas were used.

Preparation and culture of hepatocytes. Human fetal hepatocytes were prepared and characterized as described previously.[7] The cells were maintained in primary culture in medium containing arginine-deficient Eagle's minimal essential medium (Grand Island Biological Co., Grand Island, N.Y.) to suppress fibroblast

growth plus fetal calf serum (10% v/v) and antibiotics (penicillin, 1000 U/ml; amphotericin B [Fungizone], 2.5 μg/ml; and streptomycin, 1000 μg/ml) (Grand Island Biological Co.) for 24-48 hours. Thereafter cells were maintained in the presence or absence of various lipoproteins as discussed in the Results section.

Lipoproteins. Low-density lipoproteins, (density, 1.019 to 1.063 gm/ml), HDL_3 (density, 1.125 to 1.215 gm/ml), and lipoprotein-poor serum were prepared as previously described.[8] Iodine 125–iodo-LDL and [^{125}I]iodo-HDL were prepared as previously described.[9] The specific activity of [^{125}I]iodo-LDL and [^{125}I]iodo-HDL ranged from 250 to 400 cpm/ng of protein.

Lipoprotein uptake by human fetal hepatocytes. The cells were maintained in culture as previously described on day 2 or 3 of culture, the media was changed to lipoprotein-poor serum for 3 additional days. On the fifth or sixth day of culture, the cells were rinsed twice with 0.15 mol/L of NaCl. One milliliter of fresh medium containing lipoprotein-poor serum (10%, v/v) and [^{125}I]iodo-LDL or [^{125}I]iodo-HDL was added to each dish. Incubation was continued at 37° C in a humidified atmosphere of 95% air and 5% CO_2. At the end of the incubation period, the dishes were removed from the incubator and placed on ice. The medium was removed, and the cells were rinsed three times with 0.15 mol/L of cold NaCl. The cells were scraped and homogenized in 1 ml 0.15 mol/L of NaCl; an aliquot (500 μl) of the homogenate was assayed for radioactivity. Duplicate aliquots (100 μl) were assayed for protein content.

Degradation of lipoproteins by human fetal hepatocytes. To measure the degradation of [^{125}I]iodo-LDL or [^{125}I]iodo-HDL to amino acids (monoiodotyrosine), the culture medium of cells incubated in the presence of [^{125}I]iodo-LDL or [^{125}I]iodo-HDL was removed from each dish and mixed with 1 ml of trichloroacetic acid (50%, wt/vol). Three milliliters of bovine serum albumin (5 mg·ml^{-1}) were added to the acidified culture medium, and the mixture was allowed to stand for 30 minutes at 4° C. The tubes were then centrifuged at 1500 rpm for 5 minutes. An aliquot (3 ml) of supernatant fluid was mixed with 30 μl potassium iodide solution (40%, w/v) and 120 μl of H_2O_2 (30%). After standing at room temperature for 5 minutes, the mixture was extracted with 10 ml of $CHCl_3$ to remove the free iodine, and 2 ml aliquots of the aqueous layer were assayed for radioactivity. The radioactivity contained in trichloroacetic acid–soluble substances in the culture medium incubated with [^{125}I]iodo-LDL or [^{125}I]iodo-HDL in the absence of tissue was assayed. This value served as the blank and was used in the calculation of the results.

Results are expressed as nanograms of [^{125}I]iodo-LDL or [^{125}I]iodo-HDL taken up or degraded per milligram of protein per unit time, and each data point represents the mean ± SE of four replicate dishes or the average of duplicate dishes as described in the figure legends.

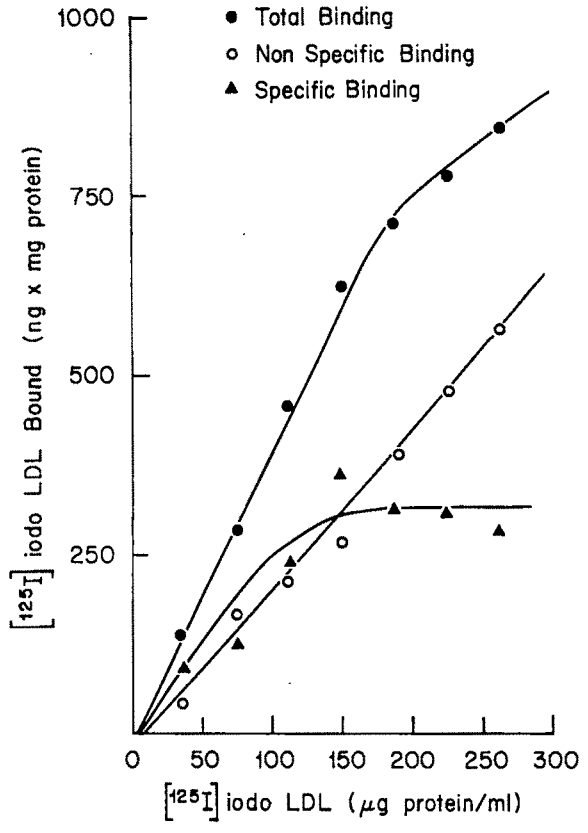

Fig. 1. The total (●), nonspecific (○), and specific binding (▲) of [^{125}I]iodo-LDL to human fetal liver membrane fractions as a function of [^{125}I]iodo-LDL concentration. Each data point represents the average of duplicate incubations.

[^{125}I]Iodo-LDL binding in human fetal liver membrane preparations. Fresh human fetal liver membrane preparations were prepared as described previously for adrenal tissues.[10] The binding of [^{125}I]iodo-LDL to liver membrane preparations was assayed as previously described for human fetal adrenal membrane preparations.[10]

Chemicals. Bovine serum albumin and trichloroacetic acid were obtained from Sigma Chemical Co. (St. Louis, Mo.). Other chemicals used were of analytic grade.

A statistical analysis of the results was performed by means of an analysis of variance followed by Newman-Keuls multiple comparison analysis. Each figure (2 through 6) was repeated two to three times and a representative experiment is presented.

Results

We first determined whether specific binding sites for low-density lipoproteins were present in membrane fractions prepared from human fetal liver tissue. The specific binding of [^{125}I]iodo-LDL as a function of the

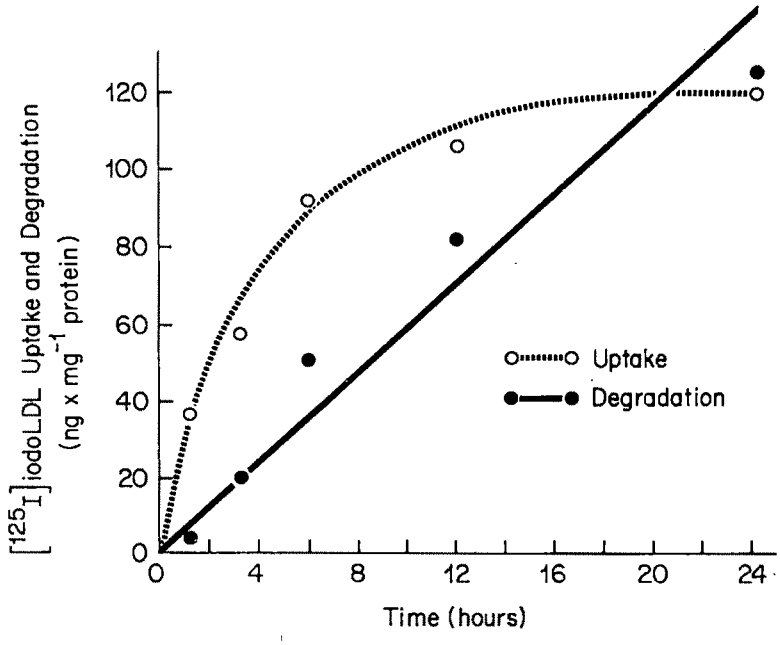

Fig. 2. Time course of uptake and degradation of [^{125}I]iodo-LDL by human fetal hepatocytes. Cells were maintained for 72 hours in the presence of medium containing lipoprotein-poor serum. Thereafter, [^{125}I]iodo-LDL (10 μg of low-density lipoprotein protein/ml) was added at time 0. Each data point represents the average of duplicate incubations.

concentration of [^{125}I]iodo-LDL in the incubation medium is presented in Fig. 1. The specific binding was computed from the difference between total binding and binding observed in the presence of excess nonradiolabeled low-density lipoprotein. From the results of these experiments, we suggest that the binding of [^{125}I]iodo-LDL is saturable, with a maximal binding capacity of approximately 300 ng of low-density lipoprotein protein/mg of membrane protein (range, 190 to 372 ng/mg; n = 9) and an apparent dissociation constant of approximately 60 μg of low-density lipoprotein protein/ml (range, 60 to 344 ng/ml; n = 9) as determined by Scatchard plot.

The uptake and degradation of [^{125}I]iodo-LDL by human fetal hepatocytes as a function of time are presented in Fig. 2. Human fetal liver cells were maintained for 72 hours at 37° C in the absence of lipoproteins lipoprotein-poor serum. [^{125}I]Iodo-LDL (10 μg of low-density lipoprotein protein/ml) was added to the culture medium at time 0. Thereafter, the rate of uptake of [^{125}I]iodo-LDL increased for 12 hours, and no further uptake was noted during the 24-hour period. Degradation of [^{125}I]iodo-LDL was detected by 1 hour and continued to increase in a linear fashion for at least 24 hours.

The effect of temperature on the uptake and degradation of [^{125}I]iodo-LDL by human fetal hepatocytes was also assessed. Cells were maintained for 72 hours at 37° C in media containing lipoprotein-poor serum. Thereafter, cells were maintained at 4° C for 1 hour, and [^{125}I]iodo-LDL (20 μg of low-density lipoprotein protein/ml) was added to the culture medium. Maximal cellular uptake of [^{125}I]iodo-LDL at 4° C was attained by 25 minutes and did not increase further (data not shown). In contrast, the degradation of [^{125}I]iodo-LDL was markedly inhibited, a finding indicating that the degradation process is temperature dependent.

Next, the effect of preincubation of human fetal hepatocytes with various concentrations of nonradiolabeled low-density lipoprotein or high-density lipoprotein on the uptake (Fig. 3) and degradation (Fig. 4) of [^{125}I]iodo-LDL was investigated. Cells were maintained for 72 hours in the presence or absence of nonradiolabeled lipoprotein. Thereafter [^{125}I]iodo-LDL (10 μg of low-density lipoprotein protein/ml) was added to the culture medium for 6 hours. Low-density lipoproteins significantly inhibited [^{125}I]iodo-LDL uptake and degradation in a dose-related fashion (Figs. 3 and 4). Both degradation and uptake were inhibited significantly by 25 μg of low-density lipoprotein protein/ml. In contrast, high-density lipoproteins did not inhibit the uptake of [^{125}I]iodo-LDL in concentrations of up to 500 μg of high-density lipoprotein protein/ml (Fig. 3). The presence of high-density lipoproteins in the preincubation medium also had a minimal influence on [^{125}I]iodo-LDL degradation (Fig. 4).

The uptake and degradation of [^{125}I]iodo-HDL by human fetal hepatocytes as a function of time are pre-

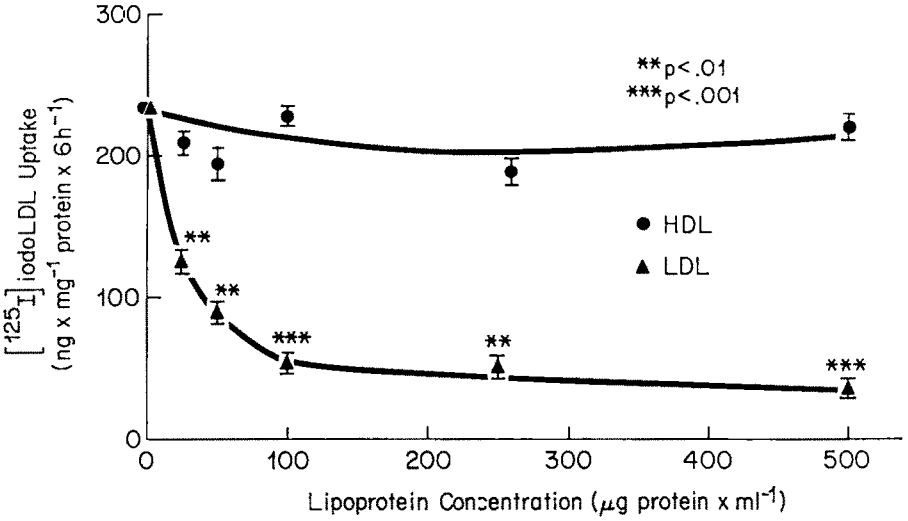

Fig. 3. The effect of lipoproteins on the rate of uptake of [^{125}I]iodo-LDL by human fetal hepatocytes. Cells were maintained for 72 hours in the presence of various concentrations of nonradiolabeled low-density lipoprotein or high-density lipoprotein. Thereafter, the cells were rinsed with fresh medium containing lipoprotein-poor serum and [^{125}I]iodo-LDL (10 μg of low-density lipoprotein protein/ml) was added to the culture medium for 6 hours. Each data point represents the mean and SE of quadruplicate dishes. (*HDL* = High-density lipoprotein; *LDL* = low-density lipoprotein.)

Cells were maintained for 72 hours in the presence of various concentrations of nonradiolabeled low-density lipoprotein or high-density lipoprotein. Thereafter, the cells were rinsed with fresh medium containing lipoprotein-poor serum and [^{125}I]iodo-LDL (10 μg of low-density lipoprotein protein/ml) was added to the culture medium for 6 hours. Each data point represents the mean and SE of quadruplicate dishes. (*HDL* = High-density lipoprotein; *LDL* = low-density lipoprotein.)

sented in Fig. 5. Cells were maintained at 37° C for 72 hours in medium containing lipoprotein-poor serum. Thereafter, [^{125}I]iodo-HDL (10 μg of high-density lipoprotein protein/ml) was added to the culture medium. The uptake of [^{125}I]iodo-HDL increased with time for 12 hours and remained constant for as long as 24 hours. In contrast, the degradation of [^{125}I]iodo-HDL was extremely low.

Finally, we investigated the effect of nonradiolabeled lipoprotein on the rate of uptake of [^{125}I]iodo-HDL by human fetal hepatocytes. Cells were maintained at 37° C in the presence of various concentrations

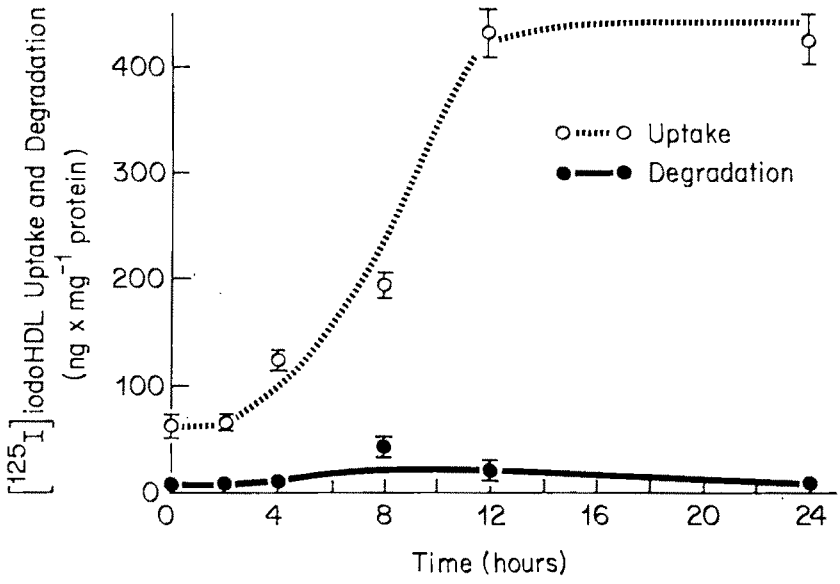

Fig. 5. Time course of the metabolism of [^{125}I]iodo-HDL by human fetal hepatocytes. Cells were maintained for 72 hours in the presence of lipoprotein-poor serum. Thereafter, [^{125}I]iodo-HDL was added to the culture medium (10 μg of high-density lipoprotein protein/ml) for 24 hours. Each data point represents the mean and SE of quadruplicate dishes.

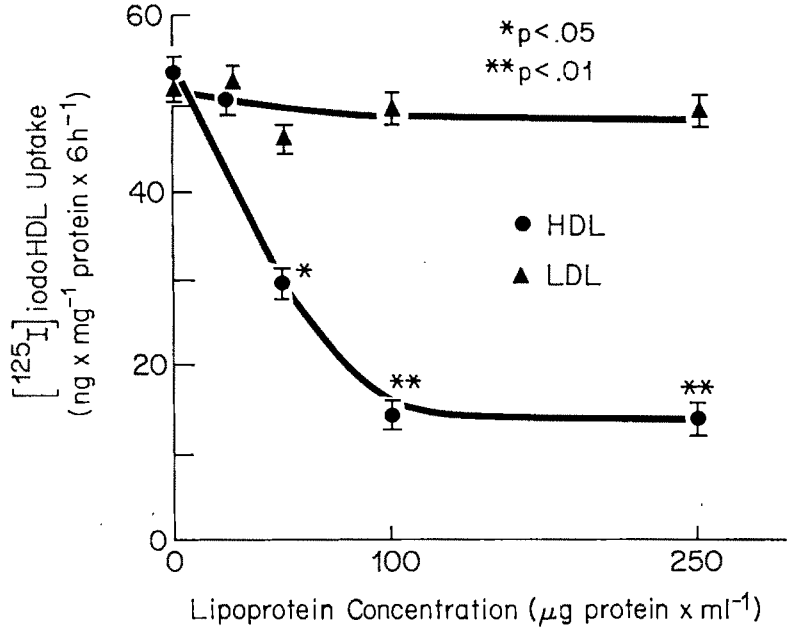

Fig. 6. The effect of lipoproteins on the uptake of [^{125}I]iodo-HDL by human fetal hepatocytes. Human fetal hepatocytes were maintained for 72 hours in the presence of various concentrations of nonradiolabeled high-density lipoprotein or low-density lipoprotein. Thereafter, the cells were rinsed with fresh medium containing lipoprotein-poor serum and [^{125}I]iodo-HDL (10 μg of high-density lipoprotein protein/ml) was added to the culture medium for 6 hours. Each data point represents the mean and SE of quadruplicate dishes. (*HDL* = High-density lipoprotein; *LDL* = low-density lipoprotein.)

of nonradiolabeled low-density lipoprotein or high-density lipoprotein for 72 hours. Thereafter, the medium was changed, and [^{125}I]iodo-HDL (10 μg of high-density lipoprotein protein/ml) was added to the culture medium for an additional 6 hours (Fig. 6). Preincubation of fetal hepatocytes with low-density lipoprotein up to 500 μg of low-density lipoprotein protein/ml had no effect on the uptake of [^{125}I]iodo-HDL

by fetal hepatocytes. In contrast, preincubation with nonradiolabeled high-density lipoproteins inhibited uptake of [^{125}I]iodo-HDL in a dose-related fashion.

Comment

In a previous investigation, we studied the effect of lipoproteins on cholesterol synthesis by human fetal hepatocytes maintained in culture.[11] We observed that low-density lipoproteins inhibited cholesterol synthesis in a dose-related fashion, which suggested that low-density lipoproteins were acting via a receptor-mediated process similar to that described for extrahepatic human fetal tissues. In the present study, we observed that human fetal liver membrane preparations exhibited saturable binding for [^{125}I]iodo-LDL. Although the affinity for low-density lipoproteins was low in human fetal lever membranes, these results were similar to those reported by Brown et al.,[5] who previously reported evidence for a binding site for low-density lipoproteins on human fetal liver membrane preparations, and by Hoeg et al.[6] in adult human liver membrane preparations. In contrast, one report demonstrated that the human adult liver contains only the presence of apolipoprotein E receptors but not apolipoprotein B receptors. Furthermore, these investigators reported that there was no significant binding of low-density lipoproteins to human adult membranes.[12] The reasons for the lack of binding of low-density lipoproteins in that study of adult liver membranes in vitro are unclear. Recently, Bilheimer et al.[3] reported that the transplantation of a liver from a normal child to a subject with homozygous familial hypercholesterolemia with defective and reduced low-density lipoprotein receptors was followed by rapid decline in low-density lipoprotein–cholesterol plasma levels and an increase in cholesterol catabolic rate of intravenously administered [^{125}I]iodo-LDL. These results suggest that the livers of adult, children, and fetuses contain receptors for low-density lipoprotein.

In the present study, we have shown that human fetal hepatocytes take up and degrade [^{125}I]iodo-LDL in a manner similar to that described for extrahepatic tissues in the human fetal adrenal, placenta, and adult corpus luteum and fibroblasts.[13] The uptake of low-density lipoproteins is followed by internalization by a process of adsorptive endocytosis. The vesicles formed by endocytosis apparently fuse with lysosomes and the protein compartment is hydrolyzed to amino acids whereas the cholesterol esters are hydrolyzed to fatty acids and cholesterol, as also reported to occur in extrahepatic tissues. The cholesterol formed may function by inhibiting endogenously formed cholesterol[11] or be reused in the formation of lipoproteins and then excreted by the liver.

We observed that nonradiolabeled low-density lipoproteins clearly inhibited [^{125}I]iodo-LDL uptake and degradation by human fetal hepatocytes in a dose-related fashion. In contrast, apolipoprotein E–free high-density lipoproteins had no significant effect on low-density lipoprotein uptake or degradation. These results were different than those reported to occur with pig hepatocytes.[14] In that study apolipoprotein E–free high-density lipoproteins inhibited low-density lipoprotein uptake but to a lesser degree than did low-density lipoproteins.

The mechanism for the regulation of the metabolism of high-density lipoproteins by cells is less clear. Evidence from our laboratory previously suggests that the human HDL_3 fraction, which primarily contains apoprotein AI and AII but no apoprotein E, stimulated cholesterol synthesis in human fetal hepatocytes.[11] Others have reported that high-density lipoprotein has the capacity to remove unesterified cholesterol from cells in culture.[2] The nature of cellular interaction and binding, as well as catabolism of high-density lipoprotein, is presently unclear.

In the present investigation, we have demonstrated that [^{125}I]iodo-HDL is taken up by human fetal hepatocytes as a function of time as was true for human fetal adrenal tissue and that [^{125}I]iodo-HDL degradation occurred at an insignificant rate as was also observed for human fetal adrenal tissue.[9] Others have reported that high-density lipoprotein binds to placental and testicular tissue and fibroblasts but that degradation was negligible.[4] In contrast, high-density lipoprotein was apparently internalized and the degradation of high-density lipoprotein was inhibited by chloroquine by cultured hepatocytes of rats and pigs.[14, 15] Utilizing pig hepatocytes, Bachorik et al.[14] reported that both apolipoprotein E–free high-density lipoprotein uptake and degradation was inhibited by both high-density lipoprotein and low-density lipoprotein. In our investigation using human fetal hepatocytes, the uptake of [^{125}I]iodo-HDL was inhibited by preincubation with high-density lipoprotein but not by low-density lipoprotein. Recently, Hoeg et al.[16] characterized high-density lipoprotein binding to human adult liver membranes but did not investigate the uptake and degradation in normal adult liver cells.

In conclusion, human fetal hepatocytes take up and degrade low-density lipoprotein in a similar fashion to that for human extrahepatic tissues. The uptake of low-density lipoprotein appears to be a receptor-mediated process, and the receptors recognizing low-density lipoprotein and high-density lipoprotein are different. Human fetal hepatocytes also take up apolipoprotein E–free high-density lipoprotein but do not degrade it, and the role of the fetal liver with respect to the clearance of high-density lipoprotein is less clear.

We thank Dr. Evan Simpson for critical evaluation of these studies, Nora Cline for skilled technical assistance,

and Lynne McDonnell and Cecilia Gabrillo for their expert editorial assistance.

The prevalence of autoantibodies in pregnant and nonpregnant women

Phillip E. Patton, M.D., Carolyn B. Coulam, M.D., and Erik Bergstralh, M.S.
Rochester, Minnesota

The frequency of autoantibodies during pregnancy was studied. Sera from 136 women (84 pregnant and 52 nonpregnant) were tested for antibodies directed against nuclear antigens, smooth muscle antigens, gastric parietal cells, mitochondria, and striated muscle by indirect immunofluorescent microscopy. Rheumatoid factor was measured by a latex agglutination test, and thyroid microsomal and thyroglobulin antibodies were measured by a hemagglutination assay. Immunofluorescence assays were considered positive if antibodies were detected at a serum dilution of 1:20. All positive samples were retested at increasing dilutions until immunofluorescence or agglutination could not be detected. The control population consisted of 52 normal, healthy, ovulatory, and nonpregnant women. The study population consisted of 84 pregnant women, none of whom had a known autoimmune disorder. The mean ages of the two groups were 32 and 26 years, respectively. The frequency of autoantibody detection was not significantly different in comparing the study (46.2) and control groups (40.5). The results did not support the hypothesis that pregnancy has an effect on the induction or suppression of autoantibody production. Previous studies that suggested differences may have been influenced by the lack of a control group. (Am J Obstet Gynecol 1987;157:1345-50.)

Key words: Autoantibodies, pregnancy, immunology

There has been little agreement on the effect of pregnancy on the production of autoantibodies. Both an increase and a decrease have been reported[1, 2] in patients with autoimmune disease. Previous studies have generally examined autoantibodies in patients with known autoimmune disorders or who had medical complications related to pregnancy. Few studies have examined autoantibodies in uncomplicated pregnancies of healthy women.

Autoantibodies have been detected in "normal" pregnant subjects[3-5] and appear to be more frequent than in nonpregnant control groups. Yet the significance of autoantibody detection during pregnancy remains unclear. One difficulty in the interpretation of previous studies is that changes in only a single autoantibody are generally reported, and a larger survey of autoantibody production during pregnancy has never been conducted. A more critical problem in many earlier reports was the lack of an adequate control group. The purpose of this study was to determine the frequency of several autoantibodies in a pregnant population and a nonpregnant control group. Medical, family, gynecologic, and reproductive histories were reviewed to define the study population adequately and determine if any historical factors were related to the presence or absence of autoantibodies.

From the Departments of Obstetrics and Gynecology and Medical Statistics and Epidemiology, Mayo Clinic.
Presented at the Thirty-third Annual Meeting of the Society for Gynecologic Investigation, Toronto, Ontario, Canada, March 19-22, 1986.

Material and methods

Subjects. Sera from a total of 136 women seen in the Department of Obstetrics and Gynecology at the Mayo Clinic from March 1983 to October 1984 were tested for autoantibodies. The study population consisted of 84 consecutive low-risk pregnant subjects admitted with uncomplicated pregnancies, and all but two had blood drawn in the third trimester. Ages ranged from 15 to 36 years, with a mean of 26 years. The nonpregnant control population consisted of 52 paid volunteers without major systemic illnesses or a known autoimmune disease. All subjects used barrier contraception and were ovulatory on the basis of basal body temperature charting or serum progesterone assay. Ages ranged from 19 to 48 years, with a mean age of 32 years. No subject in the study had a history of autoimmune thyroiditis, pernicious anemia, systemic lupus erythematosus, or other known autoimmune disease.

Histories in both control and pregnant subjects were carefully abstracted for significant medical illness, familial disease, and gynecologic and reproductive disorders. Past and current pregnancies were reviewed for outcome (abortion, stillbirth, and viable term delivery) and intrapartum and postpartum complications. Fetal

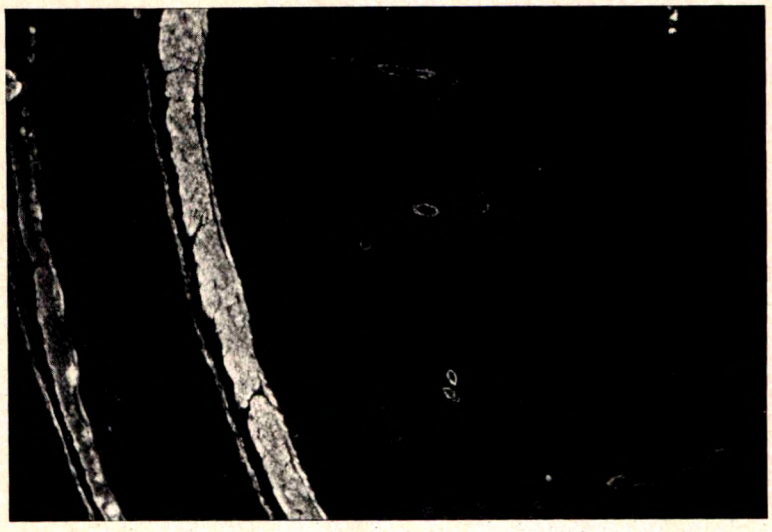

Fig. 2. Positive immunofluorescence of gastric smooth muscle.

weight, Apgar score, morbidity, and mortality were reviewed for both past and current pregnancies.

Indirect immunofluorescence. Sera were stored at −20° C until assayed. Antibodies directed against nuclei, smooth muscle, striated muscle, gastric parietal cells, and mitochondria were assayed by indirect immunofluorescent microscopy. Unfixed cryosections (4 to 5 μm) mounted on slides were incubated with a 1:20 to 1:60 dilution of the patient's serum in phosphate-buffered saline solution for 30 to 45 minutes at 22° C. Sera from patients with a documented autoimmune disease served as positive controls. A negative control (normal male) and diluent buffer control were also run in each assay. Fluorescein-conjugated goat polyvalent antisera against human immunoglobulins (IgG, IgM, κ, and λ) was the second antibody. Slides were graded on a scale of 0 to + + + + (0 equaled background immunofluorescence and + + + + equaled the fluorescence intensity of the positive control). Each slide was graded independently and blindly by two observers.

Samples were considered positive if immunofluorescence was detected at a 1:20 dilution. All positive sera were retested at increasing dilutions until immunofluorescence could not be detected.

Agglutination assays. Sera were screened for rheumatoid factor by use of a latex agglutination test (Rheumanosticon:Organon). A 1:20 or greater dilution of sera in phosphate-buffered saline solution was tested according to kit instructions.

were measured by a sensitized red cell agglutination test (Seratek: Ames). A 1:20 or greater dilution of sera in phosphate-buffered saline solution was tested according to kit instructions.

Figs. 1 and 2 are representative examples of positive autoantibodies directed against mitochondria and smooth muscle, respectively.

Statistical analysis. Statistical associations were tested with the χ^2, Fisher's exact (sparse tables), and rank-sum tests as appropriate. In view of the large number of tests preferred, a nominal p value of <0.01 was considered significant to minimize the detection of spurious associations.

Results

The finding of a single autoantibody and more than one autoantibody in the study population is presented in Table I. The finding of more than one autoantibody per subject (seen in 16 subjects) did not occur at a frequency more than expected (14.5 expected) under the assumption that the antibodies are independent. Since autoantibodies directed against mitochondria also react with gastric parietal cells, the possibility that two different autoantibodies were present in sera of subjects with positive autoantibodies directed against mitochondria was not excluded.

The frequency of autoantibodies in the total study population is presented in Table II. The autoantibody detected most frequently was the thyroid microsomal antibody. The finding of autoantibodies in the study population was not known to be associated with a documented autoimmune disease.

The study population was divided into a pregnant group and a control group (nonpregnant) to compare the frequency of autoantibodies in each group. The frequency with which at least one autoantibody was detected in the control (46.2%) and pregnant groups (40.5%) did not differ significantly. When the frequency of the most prevalent autoantibodies (i.e., those found in at least five subjects in the total study population) was compared, there was no significant difference between the two groups (Table III).

Historical events that may have been related to the finding of autoantibodies were examined to determine if any events predominated in one group. Historical events that occurred frequently in the subjects' immediate medical history (at least five times in the total study population) included rheumatoid disease and anemia. Historical events in the maternal family history that occurred frequently were cancer, diabetes mellitus, heart disease, and hypertension. Although the control group had a family history of heart disease, kidney disease, and hypertension more often than the pregnant group, none of these factors was found to be significantly associated with the detection of autoantibodies.

To determine if age and gravidity influenced the finding of autoantibodies, the study population (pregnant and nonpregnant groups) was divided into intervals of age and gravidity at the time that blood was drawn (Table IV). Neither gravidity nor age intervals were associated with the occurrence of autoantibodies. A trend for antibodies directed against nuclei and age was noted, but it was not statistically significant.

Pregnant and control subjects differed with respect to age and prior gravida. To exclude the possibility that age or gravidity may have been a bias, the study and pregnant groups were matched. Thirty of the 54 subjects were matched to a pregnant subject of like age and gravidity. When the frequency of autoantibodies was evaluated for those matched pairs, there remained no significant difference in the frequency of autoantibodies between the groups.

The outcome of prior pregnancies was evaluated with respect to the frequency of autoantibodies. Ninety-seven women had a prior pregnancy outcome (other than a therapeutic abortion) before the time that blood

was drawn. Among these subjects, prior live birth, stillbirth, or miscarriage did not correlate with the detection of autoantibodies (Table V). The association between maternal and fetal complications and the detection of autoantibodies was evaluated in subjects who had ever been pregnant. Maternal and fetal complications that occurred at least five times in pregnant subjects included premature rupture of membranes, chorioamnionitis, hypertension, oxytocin use, and fetal resuscitation. The detection of autoantibodies was not significantly associated with any of these variables.

Comment

Both cellular and humoral immunities may be altered during pregnancy. However, reports concerning changes in the immune system during pregnancy are not in agreement. In general, studies in animals and with human cells in vitro suggest a depression of cellular immune responses to viruses,[6] lymphocyte response to mitogens and allogeneic lymphocytes,[7] homograft survival, and delayed hypersensitivity[8] during pregnancy. The effects of pregnancy on humoral immunity are less clear, but immunoglobulin levels have been reported to be unchanged or slightly increased.[9]

Clinical studies also suggest that pregnancy may affect the immune system. The preponderance of autoimmune disorders in women,[10] the improvement of autoimmune disorders during pregnancy,[11] and the changes noted in autoantibody titers with pregnancy[2] imply that sex steroids or other factors may have a direct effect on the immune system.

Pregnancy may have an effect on autoantibody production, but published data are difficult to interpret. Previous studies on autoantibody detection in pregnancy that examined patients with a documented autoimmune disease describe a variety of changes in autoantibody titer. Autoantibody titers have been reported to increase,[1] decrease,[2] or remain unchanged[3] during pregnancy depending on the autoimmune disorder studied. In patients without an autoimmune disease, testing for autoantibodies has yielded conflicting results. For example, autoantibodies directed against nuclei were reported in one study to increase[5] and in another to be unchanged[4] during pregnancy in healthy women. Similarly, the prevalence of rheumatoid factor measured during pregnancy by radioimmunoassay

Table V. Prior pregnancy outcome and autoantibody occurrence

was reported to be increased[12] but unchanged when measured by an enzyme-linked immunosorbent assay.[13] It is clear that generalizations concerning the effect of pregnancy on autoantibody production are difficult to make, since autoantibody detection depends on numerous factors, including the sample population tested, frequency and interval of testing, the type of assay procedure, and the number of autoantibodies evaluated.

The purpose of the study was to compare the frequency of autoantibodies in a pregnant population with that in a control group and determine if pregnancy or other historical factors were related to the detection of autoantibodies. In the study, the control group consisted of ovulatory women without major systemic illnesses or medical disorders. Previous studies that reported an increase of autoantibodies in a "normal" pregnant population[3, 5] may have been biased by the lack of an adequate control group. Furthermore, it is unclear in these studies whether endocrine, reproductive, and other medical disorders that may have a direct effect on autoantibody production were assessed.

In the present study antibodies directed against numerous cellular antigens were determined in the pregnant population and a healthy female control group by indirect immunofluorescence and agglutination assays. Since previous studies have not performed a comprehensive survey of autoantibodies during pregnancy, an extensive panel of autoantibodies associated with frequent autoimmune disorders was screened. Most assays in pregnant subjects were performed in the third trimester because in previous studies,[4] it was suggested that the prevalence of autoantibodies and the effects of sex steroids may be greatest at that time.

When the frequency of detection of at least one autoantibody was compared between the pregnant population (40.5%) and the control group (46.2%), no statistically significant difference was noted. The frequency of detection of a single autoantibody class was also compared between the pregnant and control subjects, and no significant association of individual autoantibodies in either study group was noted.

To the best of our knowledge, no study has previously reported the percentage of subjects with positive autoantibodies in pregnant and nonpregnant groups when a large panel of autoantibodies was screened. Although the prevalence of at least one detectable antibody in the sample population may appear high, these percentages may depend on the number of autoantibodies tested and the false-positive rate of each test. If each autoantibody had a false-positive rate of 5%, one could expect that 30% of the subjects would be falsely positive on one or more of seven independent tests (probability of a positive test = $100 \times [1 - 0.95^7]$). More important, the frequency of detecting a single autoantibody, such as antibodies against nuclei, is in agreement with previous studies.[14]

Historical factors in the patient's immediate history and familial history could have a direct effect on the detection of autoantibodies. When past medical history, familial history, age, gravidity, and reproductive history were examined in the control and pregnant groups, no single historical factor was significantly associated with the presence or absence of autoantibodies. A trend in the detection of antibodies against nuclei and age was noted, but was not statistically significant.

The results of the present study do not support suggestions that pregnancy either induces or suppresses the production of autoantibodies in healthy subjects. Because the frequency of several of the autoantibodies in our study population was low, we cannot exclude the possibility that pregnancy may affect the production of these infrequent antibodies. Larger studies will be necessary to determine if an association exists. Since patients in the present study were sampled primarily in the third trimester, we cannot exclude the possibility

that autoantibody production varies with the time of gestation. For example, it has been reported that the detection of antibodies against nuclei may vary throughout pregnancy.[4] A longitudinal study with sampling before pregnancy, during pregnancy, and postpartum could help determine the effect of pregnancy on autoantibody production.

Autoantibodies that react with fetal antigens have been implicated as causes of fetal morbidity in subjects with an autoimmune disorder[1] and may play a role in the pathogenesis of repeated pregnancy loss and pregnancy-induced hypertension.[15, 16] In this study, the presence of the autoantibodies in subjects without a documented autoimmune disease did not appear to have an adverse effect on maternal or fetal well-being. In most cases in both pregnant and nonpregnant subjects, the titer of autoantibodies detected was low. The possibility that high levels of autoantibodies may have an adverse or protective effect on pregnancy or pregnancy outcomes was not determined. It should also be noted that not all antibodies associated with maternal disease or poor reproductive outcome, such as antiphospholipid antibodies or antibodies against extractable nuclear antigens, were evaluated in the present study. The prevalence of these important autoantibodies in uncomplicated pregnancies will require future investigation, and larger studies will be necessary to determine quantitative and qualitative effects of autoantibodies on maternal and fetal outcomes.

We thank Dr. Vanda Lennon for guidance and use of laboratory space and Elizabeth Cook for secretarial support.

The binding and metabolism of low-density lipoprotein by skin fibroblasts of fetuses and newborns with anencephaly

Bruce R. Carr, M.D., and C. Richard Parker, Jr., Ph.D.
Dallas, Texas

We have previously demonstrated that the fetus with anencephaly is hypercholesterolemic. The plasma levels of total cholesterol and low-density lipoprotein cholesterol are threefold greater than those of normal fetuses. We have provided evidence that elevated low-density lipoprotein cholesterol levels were caused by reduced uptake and metabolism of low-density lipoprotein by atrophic adrenal glands deficient in low-density lipoprotein receptors. The purpose of the present investigation was to determine if other tissues, namely, skin fibroblasts, of the fetus with anencephaly were also deficient in low-density lipoprotein receptors. We compared the binding and jmetabolism of low-density lipoprotein by skin fibroblasts of fetuses with anencephaly and normal subjects. Cultures of skin fibroblasts were grown to confluency. Thereafter, the medium was changed to lipoprotein-deficient serum for 24 hours. The rate of uptake and degradation of iodine 125–iodo-LDL was determined as a function of time and concentration of low-density lipoprotein. The maximal specific binding of low-density lipoprotein was also determined. The rate of uptake, degradation, and the maximal binding of low-density lipoprotein was similar in skin fibroblasts of infants with anencephaly and normal subjects. We conclude that the elevated level of low-density lipoprotein cholesterol in cord blood of fetuses with anencephaly is not caused by deficiency of low-density lipoprotein receptors and metabolism in skin fibroblasts but instead by deficiency of low-density lipoprotein receptors and metabolism by atrophic adrenal glands. (Am J Obstet Gynecol 1987;157:1351-5.)

Key words: Low-density lipoprotein, cholesterol, anencephaly

In contrast to normal pregnant women, women with fetuses with anencephaly have very low levels of plasma and urinary estrogens.[1] The low estrogen production by the fetoplacental unit of such pregnancies is the result of reduced production of fetal adrenal C_{19}-steroid precursors, especially dehydroepiandrosterone sulfate.[2, 3] The reason for the reduction in dehydroepiandrosterone sulfate production is that the adrenal glands of fetuses and newborns with anencephaly are atrophic and involuted, presumably because of low levels of circulating adrenocorticotropic hormone compared with those in fetuses with normal neural development.[4, 5]

We have previously demonstrated that the major source of fetal adrenal steroid biosynthesis is cholesterol in the form of low-density lipoprotein.[6] The use of low-density lipoprotein cholesterol involves the binding of low-density lipoprotein to a specific plasma membrane receptor, which is followed by internalization of low-density lipoprotein through a process of adsorptive endocytosis. The internalized vessicles fuse with lysosomes, and the protein component of low-density lipoprotein is hydrolyzed by lysosomal proteolytic enzymes to amino acids. The cholesterol esters of low-density lipoprotein also are hydrolyzed, and the liberated cholesterol is available as a precursor for the biosynthesis of steroid hormones and other cellular processes.[6] We have concluded that the fetal plasma level of cholesterol, and in particular low-density lipoprotein cholesterol, is determined primarily by the rate of uptake and use by the fetal adrenal gland.[2, 3] The anencephalic fetal adrenal gland has a reduced capacity to use low-density lipoprotein because of diminished adrenal low-density lipoprotein receptors.[7, 8] In infants and fetuses with anencephaly, plasma total cholesterol and low-density lipoprotein cholesterol levels are extraordinarily high, whereas dehydroepiandrosterone sulfate levels are extremely low.

In the present investigation, we sought to determine whether hypercholesterolemia, which is caused by excessive levels of low-density lipoprotein cholesterol, in fetuses with anencephaly was attributable solely to deficiencies in the low-density lipoprotein transport apparatus of the atrophic adrenal glands of such fetuses or whether there were also generalized defects in the low-density lipoprotein receptor in other tissues of the fetus with anencephaly. To this end, we investigated

the low-density lipoprotein receptor system of a representative, well-characterized tissue, namely, skin fibroblasts of normal infants and fetuses with anencephaly.

Material and methods

Skin biopsy specimens were obtained from three fetuses with anencephaly, 20 to 43 weeks' gestation, delivered by spontaneous or induced labor. Tissues were obtained in accordance with the Donors Anatomical Gift Act of the State of Texas after written consent was obtained from the parents with a consent form and protocol approved by the Institutional Review Board of The University of Texas Health Science Center at Dallas. Normal fibroblasts were obtained from the genital skin of two newborn infants undergoing circumcision, donated by Drs. J. D. Wilson and J. E. Griffin (Department of Internal Medicine, University of Texas Health Science Center, Dallas, Texas).

Cells. Fibroblasts were established from explants of skin as described by Griffin et al.[9] Cells were maintained in a humidified atmosphere of carbon dioxide (5%) and air (95%) and in media containing EMEM (Gibco, Chagrin Falls, Ohio), 10% fetal bovine serum (KC Biological, Lenexa, Kan.), 1 mmol/L of HEPES (Boehringer Mannheim Biochemicals, Indianapolis, Ind.), 2% antibiotics, antimycotics (Gibco), and 50 ng × ml^{-1} of fibroblast growth factor (BR Laboratories, Gaithersburg, Md.) until confluency was obtained.

Lipoproteins. Low-density lipoproteins (density, 1.019 to 1.063 gm × ml^{-1}) and lipoprotein-poor serum were prepared as previously described.[10] Iodine 125–iodo-LDL was prepared as previously described.[11] The specific activity of [^{125}I]iodo-LDL ranged from 300 to 500 cpm × ng^{-1} of protein.

Uptake of [^{125}I]iodo-LDL by fibroblasts. Cells were prepared and maintained as previously described. The media used was that described previously for maintaining the fibroblast cultures but fetal bovine serum was deleted and substituted with lipoprotein-poor serum (10% v/v) for 48 hours. Thereafter, the media was replaced with fresh lipoprotein-poor serum media and [^{125}I]iodo-LDL was added in various concentrations (0 to 200 μg × ml^{-1}) for various periods of time as described in the Results section. The incubation was continued at 37° C in a humidified atmosphere of 95% air and 5% carbon dioxide. At the end of the incubation period, the dishes were moved from the incubator and placed on ice. The media was removed, and the cells were rinsed three times with cold 0.15 mol/L of NaCl. The cells were removed with a rubber policeman and homogenized in 1 ml 0.15 mol/L of NaCl; an aliquot (500 μl) was assayed for radioactivity. Duplicate aliquots (100 μl) were assayed for protein content.

Degradation of [^{125}I]iodo-LDL by fibroblasts. To measure the degradation of [^{125}I]iodo-LDL to amino acids (monoiodotyrosine), the culture medium from fibroblasts incubated in the presence of [^{125}I]iodo-LDL was removed from each culture dish and mixed with 1 ml of trichloroacetic acid (50% w/v). Three milliliters of bovine serum albumin (5 mg × ml^{-1}) was added to the acidified culture medium, and the mixture was allowed to stand for 30 minutes at 4° C. The tubes were centrifuged at 1500 rpm for 5 minutes. An aliquot (3 ml) of supernatant was mixed with 30 μl of KI solution (40% w/v) and 120 μl of hydrogen peroxide (30%). After standing at room temperature for 5 minutes, the mixture was extracted with 10 ml of $CHCl_3$ to remove the free iodine, and 2 ml aliquots of the aqueous layer were assayed for radioactivity. We evaluated the extent of nonbiologic degradation of radiolabeled low-density lipoprotein in each experiment. The radioactivity contained in trichloroacetic acid–soluble substance in the culture medium incubated with [^{125}I]iodo-LDL in the absence of cells was assayed. This value served as the blank and was used in the calculation of the results.

Results are expressed as nanograms of [^{125}I]iodo-LDL taken up or degraded per milligram of protein per unit time, and each data point represents the mean ± SE of five replicate dishes.

Binding of [^{125}I]iodo-LDL by fibroblasts. The binding of [^{125}I]iodo-LDL by skin fibroblasts was determined by incubating cells in the presence of [^{125}I]iodo-LDL (200 μg × ml^{-1}) and in the presence or absence of excess nonradiolabeled low-density lipoprotein (2 mg × ml^{-1}) at 4° C to prevent degradation for a period of 6 hours. The maximal specific binding of low-density lipoprotein to skin fibroblasts was determined by substracting the total binding from the nonspecific binding (binding in the presence of an excess of nonradiolabeled low-density lipoprotein).

Chemicals. Bovine serum albumin and trichloroacetic acid were obtained from Sigma Chemical Co. (St. Louis, Missouri). Other chemicals used were of analytic grade.

Statistical analysis of the data was performed by means of an analysis of variance followed by Newman-Keuls multiple comparison analysis.

Results

The uptake and degradation of [^{125}I]iodo-LDL (20 μg × ml^{-1}) by anencephalic and normal skin fibroblasts as a function of time are presented in Fig. 1. The uptake of [^{125}I]iodo-LDL began after it was added to the culture medium, but after 4 hours there was no further net accumulation. During the first hour of incubation, the rate of degradation of [^{125}I]iodo-LDL was low, but

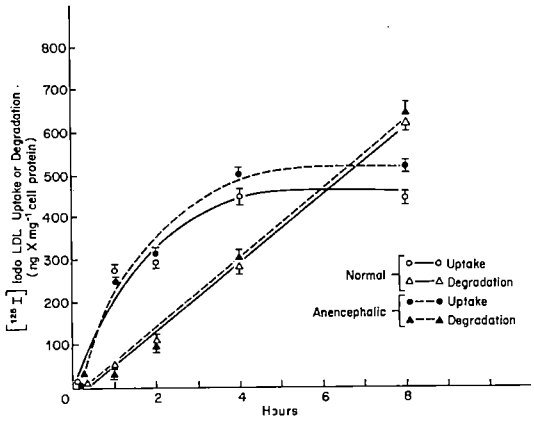

Fig. 1. Time course of uptake and degradation of [^{125}I]iodo-LDL by skin fibroblasts of normal fetuses and those with anencephaly. Cells were preincubated in medium containing lipoprotein-poor serum for 24 hours. At time zero, [^{125}I]iodo-LDL was added to the culture medium to give a final concentration of 20 μg of low-density lipoprotein protein × ml^{-1}). At the times indicated, the uptake and degradation of [^{125}I]iodo-LDL were determined in cells maintained at 37° C. The results are expressed as nanograms per milligram of protein × 6 h^{-1} of uptake or degradation. Each value presented is the mean ± SE (n = 5).

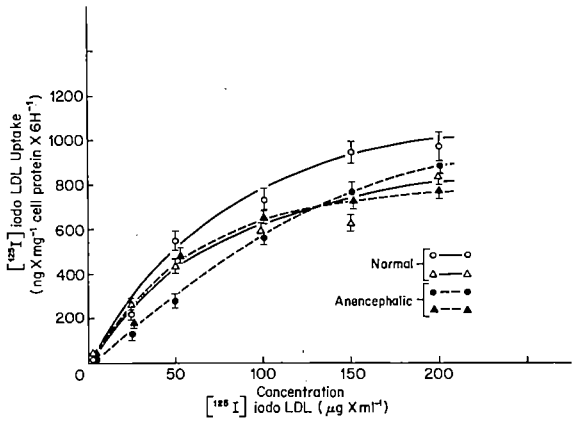

Fig. 2. Uptake of [^{125}I]iodo-LDL by skin fibroblasts of two normal newborns and two fetuses with anencephaly as a function of [^{125}I]iodo-LDL concentration in the culture medium. Cells were incubated in medium containing lipoprotein-poor serum for 24 hours; thereafter [^{125}I]iodo-LDL in various amounts was added and the incubation was continued for 6 hours at 37° C. The rate of uptake of [^{125}I]iodo-LDL was determined as described in the Material and Methods section. Each value represents the mean ± SE (n = 5).

thereafter degradation increased in a linear fashion for at least 8 hours. Based on these results, 6 hours was chosen as the standard time of incubation for further experiments in which time was not a variable. Nonspecific degradation (i.e., degradation of [^{125}I]iodo-LDL in the absence of cells) was extremely low (data not shown). The results of these experiments show that the metabolism of [^{125}I]iodo-LDL as a function of time was similar in anencephalic and normal skin fibroblasts.

The effect of [^{125}I]iodo-LDL in various concentrations (0 to 200 μg of low-density lipoprotein protein × ml^{-1}) on the rate of uptake and degradation of low-density lipoprotein by normal and anencephalic skin fibroblasts is presented in Figs. 2 and 3, respectively. In these experiments, the maximal uptake of [^{125}I]iodo-LDL as a function of [^{125}I]iodo-LDL concentration was similar in anencephalic and skin fibroblasts. Maximal uptake was achieved at concentrations of 150 to 200 μg of [^{125}I]iodo-LDL protein × ml^{-1} (Fig. 2). Likewise, the rate of degradation of [^{125}I]iodo-LDL by anencephalic and normal skin fibroblasts was similar (Fig. 3). The rate of degradation was linear with respect to the concentration of [^{125}I]iodo-LDL.

The maximal specific-binding capacity was determined in anencephalic and normal skin fibroblasts that had been previously maintained for 2 days in medium containing lipoprotein-poor serum. Afterward, fresh medium was added, and the cells were maintained for

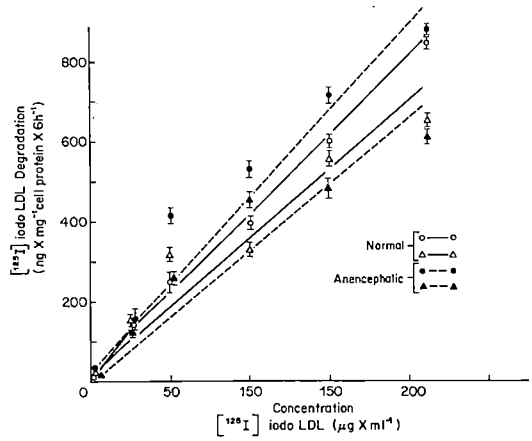

Fig. 3. Degradation of [^{125}I]iodo-LDL by skin fibroblasts of two normal infants and two fetuses with anencephaly as a function of [^{125}I]iodo-LDL concentration in the culture medium. Cells were incubated as described in Fig. 2 at 37° C. The rate of degradation of [^{125}I]iodo-LDL was determined as described in the Material and Methods section. Each value represents the mean ± SE (n = 5).

1 hour at 0° C. Next, [^{125}I]iodo-LDL (200 μg × ml^{-1}) was added in the presence or absence of excess amount of nonradiolabeled low-density lipoprotein (2 mg/ml) for 4 hours. The specific-binding low-density lipoprotein was determined as described in the Material and Methods section and is presented in Fig. 4. The maximal specific binding of low-density lipoprotein was similar in anencephalic and normal skin fibroblasts.

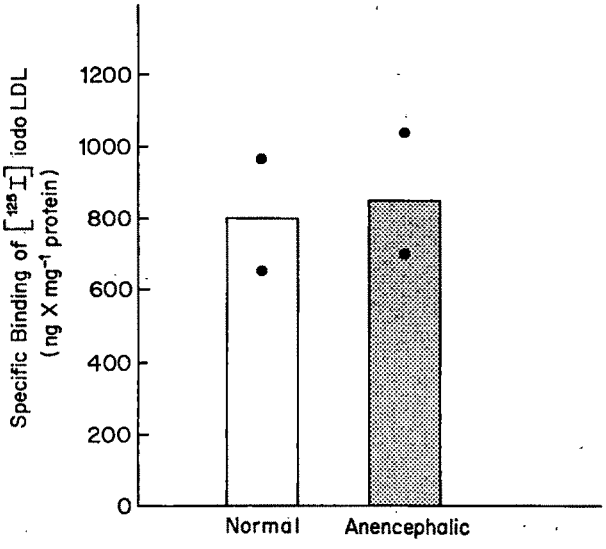

Fig. 4. Comparison of the specific binding capacity for [^{125}I]iodo-LDL of skin fibroblasts from two normal infants and two with anencephaly. The specific binding was determined as described in the Material and Methods section. The results represent the average of two experiments in which there were five replicates.

Comment

The fetus with anencephaly is hypercholesterolemic.[2,3] In fact, the cord levels of total cholesterol and low-density lipoprotein cholesterol are twofold to fourfold greater than the corresponding levels observed in normal infants. We have previously provided evidence to suggest that these differences in total cholesterol and in particular low-density lipoprotein were because of a deficiency in the number of low-density lipoprotein receptors and metabolism of low-density lipoprotein by the atrophic adrenal glands of the fetus with anencephaly.[7,8] The normal human fetal adrenal gland has the highest number of low-density lipoprotein receptors of any human tissue, as well as the tissues of other species.[12] Furthermore, the fetal zone has more low-density lipoprotein receptors than does the neocortex.[13] This partly explains (along with the low levels of adrenocorticotropic hormone), the reduced number of low-density lipoprotein receptors of the anencephalic adrenal gland, which is composed primarily of neocortex tissue.[6] As previously discussed, the uptake and metabolism of low-density lipoprotein by the adrenal gland of normal fetuses to steroid hormones appear to regulate the levels of total and low-density cholesterol in fetal plasma.[2,3]

The results of the present study demonstrate that other tissues, namely, skin fibroblasts of fetuses with anencephaly, contain a similar number of low-density lipoprotein binding sites and rates of metabolism of low-density lipoprotein as do normal skin fibroblasts. In a previous study we demonstrated that the specific activity and amount of 3-hydroxy-3-methylglutaryl coenzyme A reductase (the rate-limiting step in cholesterol biosynthesis) were very low in liver tissue of fetuses with anencephaly compared with that of normal fetuses.[14] This observation suggested that the synthesis of cholesterol in the liver of fetuses with anencephaly was suppressed by the high levels of plasma low-density lipoprotein cholesterol. These studies also suggested that anencephalic liver tissues contained low-density lipoprotein receptors. We have recently observed that anencephalic fetal hepatocytes metabolize low-density lipoprotein at rates similar to that observed for normal hepatocytes (data not shown).

In conclusion, the elevated levels of total cholesterol and low-density lipoprotein cholesterol in cord plasma of fetuses with anencephaly is caused primarily by a deficiency of low-density lipoprotein metabolism and receptors by atrophic adrenal glands. The binding and metabolism of low-density lipoprotein by other tissues, namely, skin fibroblasts and liver of infants with anencephaly and normal fetuses, are similar.

We thank Nora Cline for expert technical help and Cecilia Gabrillo for administrative assistance.

Intrapartum vibratory acoustic stimulation of the human fetus during episodes of decreased heart rate variability

Michael Y. Divon, M.D., Jeffrey J. Braverman, M.D., Denise A. Guidetti, M.D., Oded Langer, M.D., and Irwin R. Merkatz, M.D.

Bronx, New York

The effects of intrapartum vibratory acoustic stimulation during periods of decreased fetal heart rate variability were studied in 25 healthy term fetuses. Fetal monitoring and real-time ultrasound scanning were used simultaneously to detect fetal response. Vibratory acoustic stimulation was provided by an artificial larynx generating a signal at 85 dB and 85 Hz. This stimulus was applied for 5 seconds on the maternal abdomen over the fetal head after a 20-minute period of decreased fetal heart rate variability. All fetuses reacted with an immediate fetal heart rate acceleration of at least 10 bpm (range: 10 to 35 bpm, mean ± SD = 18.4 ± 7.0), and 19 fetuses also had sudden fetal body movement. A deceleration of the fetal heart rate after the initial acceleration was observed in nine fetuses (range: 15 to 70 bpm, mean ± SD = 45.5 ± 16.5). The implications of these findings are discussed in relation to the possible use of fetal vibratory acoustic stimulation for intrapartum surveillance. (Am J Obstet Gynecol 1987;157:1355-8.)

Key words: Healthy fetuses, decreased heart rate variability, vibratory acoustic stimulation

The assessment of fetal heart rate (FHR) variability and its application as a powerful intrapartum indicator of the immediate fetal condition have received increased attention in recent years. Although normal FHR variability is associated with a normal fetal outcome in most cases, decreased fetal heart rate variability commonly presents a clinical dilemma. The differential diagnosis ranges from physiologic fetal sleep to prematurity, congenital anomalies, and central nervous system depression induced by maternal medication or fetal asphyxia.[1] Because maternal medication and prematurity are tangible factors that are easily ruled out, the challenge exists in attributing decreased fetal heart rate variability to either quiet fetal sleep or fetal asphyxia.

Studies have shown that the fetus is responsive to external stimuli such as maternal glucose administration, light, sound, vibration, and physical shaking of the maternal abdomen.[2-5] These studies examined the FHR changes in response to external stimuli applied during the antepartum period. Recently it has been shown that antepartum vibratory acoustic stimulation is capable of eliciting consistent fetal responses. Healthy term fetuses responded to this stimulus by a sudden body motion (the "startle reflex") and notable heart rate acceleration.[2, 6-8]

The purpose of this study was to document fetal response to vibratory acoustic stimulus as measured by FHR and fetal movement during the active phase of labor and in the presence of decreased FHR variability.

Material and methods

Twenty-five healthy pregnant women at full-term gestation and in active labor were included in the study. Active labor was defined as the onset of strong regular uterine contractions within intervals of 5 minutes or less and a cervical dilation of at least 4 cm. No patients

were medicated. All fetuses were in cephalic presentation. Only uncomplicated singleton pregnancies with normal uterine contraction–FHR patterns were studied.

A 20-minute period of decreased FHR variability (i.e., amplitude range <6 bpm) was recorded before application of the vibratory acoustic stimulus. FHR was monitored with a fetal monitor (Corometrics 115, Corometrics Inc., Wallingford, Conn.). Fetal movement was documented by ultrasonography with a real-time scanner (Ultramark IV, ATL, linear array transducer, 3.5 MHz, Tempe, Ariz.), with the transducer placed longitudinally over the fetal chest and upper abdomen.

The fetus was observed for approximately 1 minute, and in the event of no detected fetal movement, a single 5-second vibratory acoustic stimulus was applied on the maternal abdomen over the fetal head. The vibratory acoustic stimulus measured at approximately 85 dB and 85 Hz (measured in air at a distance of 1 m) was generated by an artificial larynx (Model 5C, Western Electric). Fetal movement was defined as a sudden movement of the fetal body (i.e., startle reflex) occurring during the stimulus interval or within 2 seconds of its cessation.[7] The same examiner conducted all tests.

Results

All fetuses delivered in this study were deemed healthy on the basis of Apgar scores and physical examination. No newborn infant had an Apgar score of less than 8 at 5 minutes. All fetuses were appropriately grown and had an adequate amount of amniotic fluid. Every fetus uniformly showed an initial FHR increase during or immediately after the vibratory acoustic stimulus of at least 10 bpm. The increase in FHR measured 18.4 ± 7.0 (mean ± SD) bpm for a duration of 43.4 ± 48.4 seconds. The range for FHR increase was 10 to 35 bpm and its duration spanned from 5 to 150 seconds (Table I and Fig. 1, *A*).

In nine fetuses the initial FHR increase was followed by a FHR deceleration of 45.5 ± 16.5 bpm (mean ± SD) for 25.5 ± 19.2 seconds. The range of FHR decrease was 15 to 70 bpm for a duration of 10 to 60 seconds (Fig., 1, *B*). Three of these nine fetuses had associated umbilical cord problems.

Fetal movement occurring during the stimulus or within 2 seconds of its cessation was observed in 19 of 25 patients (Table I). No fetal movement was detected during the 1-minute observation period before stimulus administration.

In all patients fetal movement was associated with an increase in FHR. In six patients, however, the increase in fetal heart rate was not associated with simultaneous fetal movement. There was also no correlation between the increase and duration of FHR changes and the presence of fetal movement. Among the 12 fetuses who responded with an acceleration of more than 15 bpm and 15-second duration, five had no fetal movement. Only one of the 13 fetuses who responded to the stim-

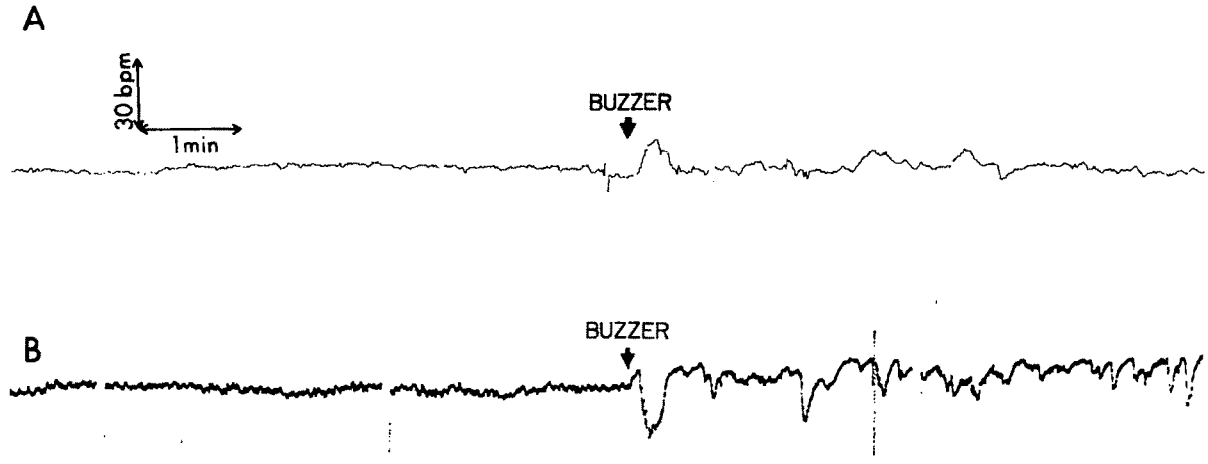

Fig. 1. A, A typical acceleration of the FHR in response to vibratory acoustic stimulation. **B,** A typical FHR deceleration after an initial acceleration in response to vibratory acoustic stimulation.

ulus with a FHR acceleration of 10 to 15 bpm had no fetal movement.

Comment

The results of this study showed that intrapartum vibratory acoustic stimulation of healthy term fetuses during episodes of decreased FHR variability evoked an immediate FHR acceleration of at least 10 bpm. These results were demonstrated in all fetuses tested. Nine of the 25 fetuses demonstrated a FHR deceleration after the initial acceleration. Fetal movement in response to this stimulus was less consistent than the FHR response but was still elicited in 19 of the 25 study patients.

Recent studies have shown that human fetal activity is strongly correlated with behavioral states. Several studies identified recurrent cycles of normal and decreased FHR variability in healthy near term pregnancies.[1] Similarly, consecutive episodes of reduced and normal FHR variability consistent with cycles of quiet and active behavior were found in active labor.[9]

All fetuses were stimulated after a 20-minute period of decreased FHR variability and demonstrated an immediate change in FHR and fetal movement in response to vibratory acoustic stimulation. Spencer et al. studied healthy term fetuses in active labor and showed that the mean duration of episodes of decreased FHR variability was 25 minutes. Since all fetuses evaluated in the present study were healthy by outcome criteria, it is likely that the decrease in FHR variability was associated with a fetal sleep state and that our observations recorded the response of the healthy "sleeping" fetus to vibratory acoustic stimulus.

FHR and fetal movement were the two parameters used to evaluate fetal response to vibratory acoustic stimulus in this study. In an antepartum study, Leader et al.[2] showed that FHR and fetal movement are variables that respond independent of each other. In the present study, no correlation existed between changes in FHR and the presence of fetal movement. However, our ability to assess the value of fetal movement was limited because no fetus responded to vibratory acoustic stimulation by fetal movement alone. Six fetuses responded to the stimulation by FHR acceleration with no concomitant fetal movement. It is, of course, possible that fetal movement occurred in alternative planes to the one observed by the real-time ultrasound scanner. It is also possible that the increase in FHR was caused by a fetal stress reaction with a concomitant increase in sympathetic activity and no fetal movement.[11]

The presence of spontaneous FHR accelerations during labor is well correlated with positive fetal outcome; yet, their absence is poorly associated with fetal distress.[11,12] Several studies suggest the use of external fetal stimulation as a way to evoke FHR accelerations. However, it has yet to be determined whether such evoked accelerations are as predictive of good fetal outcome as are spontaneous accelerations. In the study of Clark et al., all fetuses who responded to scalp stimulation with a FHR acceleration were vigorous at birth. Smith et al.[6] used vibratory acoustic stimulation of the fetus and showed that the evoked reactive nonstress test was as predictive of fetal health as the spontaneous nonstress test.

In the present study, all fetuses responded with an immediate FHR acceleration and fetal outcome was uniformly good. A possible explanation for this increase in FHR may be provided by partial occlusion of the umbilical vein caused by fetal movement. This occlusive event may precipitate a decrease in fetal blood pressure and acute hypoxia that results in reflex stim-

ulation of the autonomic nervous system. If complete occlusion occurs in the fetus without acidosis, the initial FHR acceleration is likely followed by a cardiac deceleration.[14] Total occlusion may occur when an obvious umbilical cord problem is present. In the present study, the nine decelerations observed caused by the stimulus were preceded by an increase in the FHR. Three of these patients had a clear cord problem on delivery. As expected, none of these fetuses was asphyxiated.

Ohel et al.[15] used intrapartum vibratory acoustic stimulation in cases of normal and abnormal FHR patterns. Their results indicate a significantly greater incidence of acceleration deceleration in FHR responses in fetuses with abnormal FHR tracings compared with fetuses with normal FHR tracings. Immediate FHR deceleration or zero response triggered by external stimulation was related to poor fetal outcome by Read et al.[3] Likewise, Luz et al.[16] suggested that a fetus may lose its ability to respond to an external sound or vibration stimulus before other signs of fetal distress are present. The possibility of generating a cardiac deceleration by evoking fetal responses and using this information toward differentiating umbilical cord compression from placental insufficiency is intriguing and warrants a prospective evaluation.

Postprandial walking exercise in pregnant insulin-dependent (type I) diabetic women: Reduction of plasma lipid levels but absence of a significant effect on glycemic control

Dorothy Reycroft Hollingsworth, M.D., and Thomas R. Moore, M.D.
La Jolla, California

In this study 42 pregnant women with type I diabetes and 28 nondiabetic controls were recruited to participate in a postprandial walking exercise program. Exercise patients were instructed to walk 20 minutes (1 mile) after each meal and were divided into two groups: group 1 were normal nondiabetic controls and group 2 were women with type I diabetes. There were two nonexercise comparison groups: group 3, nondiabetic controls, and group 4, women with type I diabetes. Diabetic women were followed weekly in an intensive perinatal program. Glycemic control was assessed by serial hemoglobin A_1 concentration measurements, home blood glucose monitoring, 24-hour glucose profiles, and 24-hour quantitative urinary glucose loss. Glycemic control was modestly but not significantly superior in the diabetic exercise group 2 compared with the diabetic nonexercise group 4. Exercise was associated with lower fasting cholesterol and triglyceride values in both controls and diabetic women, with significantly lower fasting plasma triglyceride levels in the diabetic exercise group ($p < 0.02$). There were no adverse effects of postprandial walking exercise in mothers or infants. (Am J Obstet Gynecol 1987;157:1359-63.)

Key words: Pregnancy, type I diabetes, exercise, triglyceride

In pregnant insulin-dependent (type I) diabetic women, exercise has not been a standard therapeutic recommendation to accompany insulin administration and dietary recommendations. Moreover, the American College of Obstetricians and Gynecologists[1] has defined a group of risk factors, including diabetes, as relative contraindications for vigorous physical activity during gestation. In contrast, moderate exercise is a usual recommendation for normal pregnant women, and guidelines for various types of physical activity have been proposed.[1, 2]

Several groups of investigators[3-8] have published optimistic reports of the effect of short-term exercise on glucose control in nonpregnant individuals with type I diabetes. Others, however, have failed to document a beneficial effect of physical exercise or training on glycemic control in individuals who have inadequate pancreatic β cell secretion of insulin.[9-11] Moreover, adverse metabolic and hormonal effects occur with exercise in diabetic patients who are in poor control.[12]

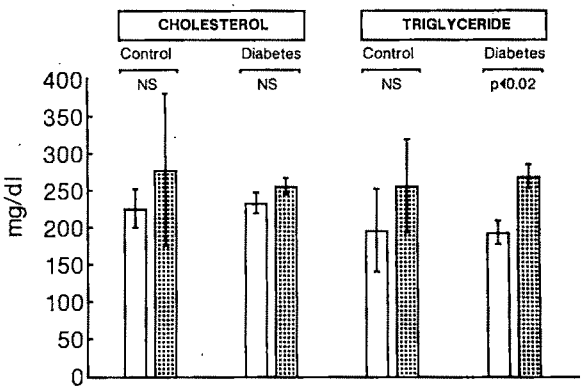

Fig. 1. Fasting plasma cholesterol and triglyceride levels in pregnant normal and type I diabetic women at 35 to 38 weeks' gestation. Exercise patients are represented by the *open bars* and nonexercise patients are represented by the *stippled bars*. Triglyceride values were significantly lower in diabetic women who exercised ($p < 0.02$). The *bars* represent the standard error of the mean.

Many young insulin-dependent diabetic women are actively engaged in sports programs and recreational forms of exercise. They frequently wish to continue these activities during pregnancy. At present, there are no published reports of the effects of prolonged mild,

moderate, or endurance types of exercise throughout pregnancy on trained, untrained, or physically fit or unfit diabetic women without residual β-cell function.

Our purpose was to assess the effect of postprandial walking exercise in pregnant, untrained, normal, and diabetic women and their infants.

Material and methods

Subjects. Forty-two women with insulin-dependent (type I) diabetes (fasting plasma C-peptide levels <1.0 ng/dl) were recruited from the Diabetes in Pregnancy Clinic at the University of California, San Diego Medical Center (UCSD) and randomly assigned to a walking exercise protocol or control group. A comparison group of 28 normal pregnant women were referred from UCSD primary obstetric care clinics and private obstetricians. All subjects were of normal weight and similar chronologic and gestational ages. Informed consent was obtained from each participant.

Protocol. All subjects were admitted to the General Clinical Research Center (GCRC) in the late first or early second trimester, serially at 21 to 27 and 35 to 38 weeks' gestation, to assess diabetic control as indicated by hemoglobin A_1 concentrations,[13] mean 24-hour glucose values, 24-hour quantitative urinary loss of glucose, and fasting plasma lipid levels[14] as previously described.[15] During the baseline study period, each diabetic patient received instructions in a diabetic diet[16] and each normal pregnant subject was placed on the diet recommended for pregnancy.[17]

Exercise and nonexercise patients were given walking pedometers that were appropriately calibrated to their strides. Subjects in the exercise protocol (group 1, normal women; group 2, women with type I diabetes) were instructed to walk 20 minutes after each meal and to record the pedometer reading for each period and at bedtime. Controls in the nonexercise groups (group 3, normal women; group 4, women with type I diabetes) were given no activity instructions, but requested to record the pedometer reading each night at bedtime. All patients kept daily compliance records for both exercise and dietary intake, adapted from our previously published method for dietary compliance.[18] Information recorded on the compliance forms concerning extraneous activity and nocturnal pedometer readings permitted an assessment of activity among and between groups.

All diabetic women were followed weekly in the UCSD Diabetes in Pregnancy Clinic for obstetric care, to review results of home blood glucose monitoring (four times daily) and for adjustments in insulin doses and diet. We assessed the daily exercise and dietary compliance forms at each visit.[18] Normal pregnant women were followed by their primary physicians and they brought or mailed their exercise and dietary records to the GCRC each week. Data were analyzed by Student's *t* test and group *t* tests. Random variation is reported as ±1 SD or SEM as indicated. All p values are two tailed.

Results

Observations. In the diabetic exercise group (group 2), one subject had a spontaneous abortion before walking exercise was initiated and four withdrew during the course of the study. Among diabetic controls (group 4), there were two spontaneous abortions before normal activity was monitored and one patient dropped out. In the nondiabetic comparison, groups 1 and 3, four women in each group withdrew from the study.

The mean (±SD) gestational age on entry into the program was 12.7 ± 7 weeks for diabetic exercise group 2, versus 12.3 ± 3 weeks for diabetic control group 4. The duration of study was 24 ± 4 weeks for group 2 and 22 ± 6 weeks for group 4. Nondiabetic controls were followed for a similar period. As shown in Table I, there were no differences among the four groups in age, prepregnancy weight, or weight gain during gestation. Length of gestation was shorter in diabetic patients than in nondiabetic controls ($p < 0.001$). The range of gestational ages in diabetic

women at delivery was 33 to 38.5 weeks in the exercise group and 34 to 40 weeks in the nonexercise group (not significant). The lower gestational age in diabetic versus nondiabetic groups was a reflection of early delivery for pregnancy-induced hypertension, fetal distress, and failed inductions of labor in earlier elective delivery.

Normal women who exercised (group 1) were highly motivated; 11 of 12 subjects exceeded the exercise protocol and eight (66%) walked more than 5 miles a day. This was significantly more walking exercise than the amount performed by the group 3 nondiabetic, nonwalking controls ($p < 0.01$) or women with type I diabetes who exercised (group 2), who in turn walked appreciably more than diabetic women who received no walking instructions (group 4; $p < 0.003$).

Diabetic control and insulin requirements. Table II presents an assessment of diabetic control with measurements of three variables: hemoglobin A_1 concentrations, mean 24-hour blood glucose values, and 24-hour urinary loss of glucose on entry and at completion of the study.

In both diabetic groups there was a striking and significant improvement in glycemic control. The change from baseline to the end of study was somewhat better in the exercise group, but the differences failed to reach statistical significance ($p < 0.06$).

Total insulin doses at baseline and at end of study were almost identical in groups 2 and 4 (Table II). Women in diabetic exercise group 2 did not require less insulin or have a smaller increase in their insulin dose during pregnancy compared with nonexercising diabetic subjects (group 4).

Fasting plasma cholesterol and triglyceride levels. The most interesting and potentially important finding in this study was the observation of lower fasting plasma cholesterol and triglyceride values in both normal and diabetic exercise groups (Fig. 1). In type I diabetic exercise patients (group 2), mean (±SEM) fasting plasma triglyceride levels were significantly lower than those in nonexercising diabetic controls (196 ± 16 versus 269 ± 23 mg/dl; $p < 0.02$). This was in contrast to the similar levels obtained at baseline (109 ± 67 versus 116 ± 39 mg/dl, not significant).

Maternal outcome. In this relatively small study there were no statistically significant differences in maternal complications of pregnancy in diabetic or comparison groups (Table III). We did observe, however, more episodes of preterm labor (20%) among the 25 women who exercised than in the controls (3.4%). Eleven of 12 normal exercise controls (including the three with preterm labor) exceeded the exercise protocol (range 2.9 to 10.4 miles/day). In the diabetic exercise group (range 3.0 to 6.3 miles/day), the three subjects with

preterm labor walked a mean of 4.8, 4.1, and 6.3 miles/day and were delivered in labor at 33, 34, and 35 weeks' gestation.

In our tightly controlled pregnant diabetic women, hypoglycemia, usually mild, occurred in both groups but was not increased in women who walked.

The cesarean section rate was high in both diabetic groups (group 2, seven [54%] and group 4, 17 [81%]). In the diabetic exercise group, cesarean section was performed for fetal distress in three patients, for failure to progress in labor in two, and for malpresentation in two others. In the nonexercise group, three women had a repeat cesarean section, four failed to progress in labor, three had cephalopelvic disproportion, and in two there was failed induction of labor. In the remaining cases, pregnancy was complicated by hypertension (two patients), breech presentation (one), or fetal distress (two). One normal pregnant woman who exercised had a cesarean section for failure to progress in labor.

Outcome of infants. Diabetic exercise subjects (group 2) had smaller placentas (509 ± 128 versus 552 ± 115 gm [$\bar{x}$ ± SD]; not significant) and infants with lower birthweights (3140 ± 658 versus 3582 ± 819 gm; not significant) and lengths (48.7 ± 2.7 versus 51.1 ± 3.6 cm; not significant). There was no difference in body mass index (infant birth weight/length^3) or placental index (placental weight/infant birth weight, or placental weight/body mass index) in the infants of the two groups.

In the 20 normal nondiabetic women there was no discernible effect of walking exercise on placental weight, gestational age, infant birthweight, length, or head circumference.

Table IV shows the complications in all four groups of infants. Diabetic women who exercised had fewer infants with neonatal hypoglycemia, hypocalcemia, hyperbilirubinemia, or macrosomia. One infant had a minor malformation. In the diabetic control group there were minor malformations in two infants and major malformations, one fatal, in two others.

Comment

This is the first study to examine the efficacy of measured walking exercise throughout pregnancy in untrained women without residual pancreatic β-cell function and in normal nondiabetic controls. Walking exercise was selected because it requires no expense or special equipment and can be engaged in by all pregnant women who do not have specific obstetric or diabetic contraindications.[19]

Our study was performed in an ambulatory high-risk obstetrics clinic that uses an intensive team approach, home blood glucose monitoring, weekly clinic visits for assessment of 24-hour urinary loss of glucose, and assessment of dietary and exercise records. In this setting we found somewhat better control of diabetes in type I diabetic women who exercised. However, analysis of end point quantitative measurements and change values failed to demonstrate a significant difference in glycemic control between diabetic groups.

Our results support the experience of others[10, 20-22] who have reported no objective evidence to support the beneficial effect of exercise or physical training on glycemic control in type I (insulin-dependent) nonpregnant diabetic patients. Exercise appears to be effective in normalizing glucose tolerance only in patients who still have an adequate capacity to secrete insulin and in whom insulin resistance is the major cause for abnormal glucose tolerance.[11] Thus it is perhaps reasonable to suggest that exercise might be more beneficial in pregnant women with type II diabetes (noninsulin dependent, but "insulin requiring" during pregnancy), as suggested by Artal and Wiswell,[23] and in obese subjects with gestational carbohydrate intolerance (gestational diabetes, GDM) and hyperinsulinemia.[24]

The observation of an apparent increase in preterm labor in the exercise groups should alert others who are engaged in studies of exercise in pregnancy to this possibility. Additional data concerning this complication are needed in a larger group of subjects.

Are the lower lipid levels in pregnant diabetic women who exercise important? Wallberg-Henriksson et al.[10]

have reported a modest decrease in total cholesterol and low-density lipoprotein triglyceride levels with daily exercise training. During pregnancy, marked endogenous hypertriglyceridemia occurs.[21, 25] Our exercise study showed significantly decreased plasma triglyceride values in the diabetic exercise group ($p < 0.02$) and lower fasting cholesterol and triglyceride levels in both diabetic and nondiabetic exercise subjects. One might speculate that lower lipid levels altered the nutrient supply transported to the fetus to account for the somewhat smaller babies of comparable gestational ages in the diabetic exercise group. The effect of exercise on the umbilical dietary supply in normal and diabetic pregnancies has not been tested by clinical investigations in humans.

In conclusion, in an intensive perinatal diabetes program, postprandial walking exercise did not significantly improve glycemic control in women with type I diabetes. In diabetic women, exercise was associated with significantly lower fasting plasma triglyceride levels and no increase in complications in mothers or infants.

We thank the UCSD Clinical Research Center staff for their assistance with the metabolic studies; Cindy Oldenburg, Sandy Kohl, and Honoré Murphy, nurse clinicians, who coordinated the exercise program; and Ms. Paula Holder and Mrs. Del Alsobrook for editorial assistance.

Restriction fragment length polymorphisms of the insulin gene hypervariable region in gestational onset diabetes mellitus

Carole Ober, Ph.D., Candace J. Wason, R.N., M.S., Kelly Andrew, B.S., and Sharon Dooley, M.D.

Chicago, Illinois

Restriction fragment length polymorphisms in the insulin gene hypervariable region are compared among 93 women with gestational onset diabetes mellitus and 146 women with normal glucose tolerance during pregnancy. No significant differences in gene or genotype frequencies were observed in the overall sample ($p > 0.50$). However, an increased frequency of one allele (class 1) was observed among nonoverweight patients with gestational onset diabetes mellitus with elevated fasting plasma glucose levels compared with age-, race-, and parity-matched control subjects ($p = 0.061$). These data suggest that gestational onset diabetes mellitus is a heterogeneous disorder with respect to both genotypic and phenotypic characteristics, and that restriction fragment length polymorphisms near the insulin gene may serve as a molecular marker for susceptibility to gestational onset diabetes mellitus only in some women. (AM J OBSTET GYNECOL 1987;157:1364-8.)

Key words: Gestational diabetes, insulin gene, restriction fragment length polymorphism analysis, genetic heterogeneity

Diabetes mellitus is a heterogeneous group of disorders that share abnormal glucose tolerance as a common feature. Because the molecular bases of these disorders are unknown, they are generally divided into two major subgroups based on insulin requirements. Insulin-dependent (type 1) diabetes mellitus is characterized by absence of insulin production, associations with other autoimmune disorders, the presence of islet cell antibodies, and associations with human leukocyte antigens HLA-DR3 and HLA-DR4. Thus type 1 diabetes mellitus is thought to have an immunologic pathogenesis in genetically susceptible individuals. Noninsulin-dependent (type 2) diabetes mellitus is characterized by inadequate insulin production, resistance to insulin action, or both. Type 2 diabetes mellitus is not associated with human leukocyte antigens, although twin and family studies suggest that it has a genetic etiology. Genes conferring susceptibility to type 2 diabetes mellitus have not been identified.

Gestational onset diabetes mellitus, defined as "glucose intolerance of varying severity with onset or first recognition during pregnancy,"[1] is generally considered to be a variant of type II diabetes mellitus. However, it is becoming increasingly evident that gestational onset diabetes mellitus is a heterogeneous disorder with regard to clinical and phenotypic characteristics as well as progression to overt diabetes mellitus under nongravid conditions.[2-5] Recent finding of HLA-DR3 and HLA-DR4 associations and islet cell antibodies in some, but not all, cases of gestational onset diabetes mellitus[2, 3] suggest that some cases may represent a slowly evolving form of type 1 diabetes mellitus. Thus the pathogenesis and underlying genetic susceptibility to gestational onset diabetes mellitus may also be heterogeneous.

The genes conferring susceptibility to gestational onset diabetes mellitus are unknown. However, several genes that either directly or indirectly regulate carbohydrate metabolism have been isolated and are thus amenable for study. These include the insulin,[6, 7] insulin receptor,[8] and glucose transporter[9] genes. It is possible that variants of any of these candidate genes could contribute to the glucose intolerance of gestational onset diabetes mellitus. Our strategy has been to look for a restriction fragment length polymorphism that is a molecular marker for a diabetogenic gene, if it exists. Similar approaches have been used to identify deoxyribonucleic acid (DNA) markers for other human genetic disorders, including single gene defects such as Huntingtons disease[10] as well as polygenic disorders such as atherosclerosis.[11] In our initial studies we examined the

role of the insulin gene in the etiology of gestational onset diabetes mellitus.

The human insulin gene has been cloned, sequenced, and localized to the short arm of chromosome 11 (11p15).[6, 7, 12] A region containing variable numbers of tandomly repeated oligonucleotides has been identified in the 5′-flanking region, about 365 base pairs upstream from the initiation site of insulin transcription.[6] This hypervariable region has been grouped into three size classes, or alleles, designated as class 1, class 2, and class 3. The class sizes correspond to approximately 570, 1320, and 2470 base pairs, respectively. The smallest, class 1 allele is the most common allele in all populations studied. The intermediate size, class 2 allele is rare in whites but occurs in low frequencies (about 10%) in blacks in the United States. The largest, class 3 allele is common in whites and blacks in the United States, but rare in Asians of Japanese and Chinese descent.[13]

Because the structure of DNA in the 5′-flanking region of many genes plays a role in modulating rates of transcription, the relationship between the insulin gene hypervariable region and types 1 and 2 diabetes mellitus has been explored. Initial studies showed an association between the class 3 allele and type 2 diabetes mellitus,[14-16] but later studies failed to confirm these findings.[17, 18] Rather, recent surveys have revealed significant associations between the class 1 allele and types 1 and 2 diabetes mellitus in Caucasians (reviewed in reference 13). Based on pooled data from five studies, the frequencies of the class 1 allele in type 1 diabetes mellitus, type 2 diabetes mellitus, and nondiabetics were 0.87, 0.75, and 0.70, respectively.[13] Based on these data, Bell et al.[13] estimated that the class 1 allele confers a relative risk of 1.3 for type 2 and of 3.3 for type 1 diabetes mellitus. The latter is comparable to the risk associated with HLA-B8. The physiologic or genetic bases for these associations are unknown.

The relationship between the insulin gene hypervariable region and gestational onset diabetes mellitus has not previously been studied.

Material and methods

Study population. All subjects were derived from patient populations at Prentice Women's Hospital and Maternity Center of Northwestern Memorial Hospital and Northwestern University Medical School. All women attending Prentice Ambulatory Care Obstetric Clinics are routinely screened for gestational onset diabetes mellitus between 24 and 28 weeks' gestation. Glucose tolerance testing is offered to all women with glucose values >129 mg/dl 1 hour after a 50 gm glucose load. Diagnosis of gestational onset diabetes mellitus is made on the basis of oral glucose tolerance testing according to the criteria of O'Sullivan and Mahan.[19]

Women diagnosed with gestational onset diabetes mellitus through Prentice Ambulatory Care screening programs were enrolled for study. Control subjects were ascertained from among women with glucose values <130 mg/dl on the routine screen or with all four normal points on the glucose tolerance test. One to two control subjects were selected for each subject with gestational onset diabetes mellitus, matched for age (±2 years), ethnic group (black, white, hispanic), and gravidity (primigravid, multigravid).

All patients with gestational onset diabetes mellitus and the control subjects were interviewed by one of two investigators (C. O., C. W.), during which time personal and family history information were ascertained (including prepregnancy weight, height, birth weight of subject, birth weight of index pregnancy, family history of diabetes mellitus, reproductive history, oral contraceptive use, and cigarette use). One blood sample for DNA analysis was collected from each participant.

DNA analysis. Genomic DNA was prepared from 15 ml of EDTA-treated whole blood as described[6] and stored in solution at 5° C. DNA samples were digested to completion with restriction endonuclease *Rsa* I following manufacturer's (Boehringer Manheim Biologicals, Indianapolis, Indiana) directions, separated by electrophoresis on 1% agarose, and transferred to nitrocellulose.[20] The cloned probe ph*ins*96 (kindly provided by Dr. Graeme Bell, Howard Hughes Institute, University of Chicago, Chicago, Illinois) was ^{32}P labeled by nick translation[21] and hybridized to nitrocellulose-bound DNA at 42° C with 50% formamide, 5X SSC (0.75 mol/L NaCl, 0.075 mol/L NaCi), 10% dextran sulfate, 20 mmol/L sodium phosphate, 2X Denhardt's solution, 0.1% sodium dodecyl sulfate, and 100 μg/ml salmon testes DNA for 48 hours. Filters were washed at 37° and 65° C, each for 1 hour in 0.1% sodium dodecyl sulfate and 0.1X SSC. Hybridized blots were exposed to XRP-1 x-ray film (Kodak) with intensifying screens (Dupont Lightening Plus) at −80° C for 5 days.

An autoradiograph of *Rsa* I–digested DNA hybridized to ph*ins*96 is shown in Fig. 1.

Statistical analysis. Associations between genotypes at the insulin gene hypervariable region and gestational onset diabetes mellitus were measured by the Maentel-Haenzel χ^2 test, stratified by racial group.[22] Allele frequencies between patients with gestational onset diabetes mellitus and control subjects were compared by a z test. To elucidate the potential confounding effects of phenotypic heterogeneity in gestational onset diabetes mellitus, subjects were further stratified on the basis of fasting plasma glucose value on the oral glucose tolerance test[23] and body mass. Patients with gestational onset diabetes mellitus with fasting plasma glucose values below the upper limits of normal for pregnancy (105 mg/dl)[19] were analyzed separately. A body mass index was calculated as: prepregnancy weight

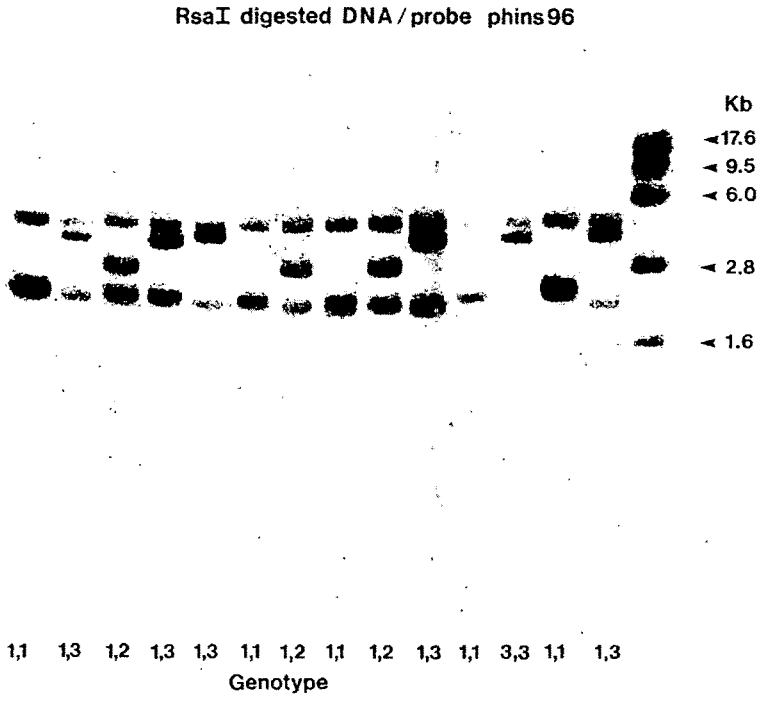

Fig. 1. Autoradiogram of *Rsa* I–digested DNA hybridized to ^{32}P-labeled ph*ins*96. The class 1 allele appears as an approximately 2 kb band and the class 3 allele as an approximately 3.8 kb band; the class 2 allele is of intermediate size. All individuals have a common 4 kb band.

(kg)/height (m)^2. A body mass index ≥24 was considered overweight. Because patients with gestational onset diabetes mellitus and control subjects were matched for race, racial groups were pooled in the latter analysis.

Results

Ninety-three patients with gestational onset diabetes mellitus and 146 control subjects were enrolled for study between May 1985 and December 1986. The numbers of subjects, mean ages at delivery and numbers of pregnancies, and proportion of subjects with a first-degree relative with diabetes mellitus are shown in Table I for each ethnic group. Mean age and number of pregnancies were similar among the three ethnic groups. Our observation of increased frequency of diabetes mellitus among first-degree relatives of patients with gestational onset diabetes mellitus compared with control subjects is consistent with other reports.[3, 21]

Genotype frequencies did not differ among subjects, within each ethnic group, or in blood analysis stratifying by ethnic group ($\chi^2_{mh} = 0.007$; $p > 0.95$; Table II). However, gene frequencies differed among phenotypic subclasses of gestational onset diabetes mellitus (Table III). The frequency of the class 1 allele was increased among patients with gestational onset diabetes mellitus in group 3 (elevated fasting plasma glucose, nonoverweight) compared with their matched control subjects ($Z = 1.55$, $p = 0.061$). The relative risk associated with the 1,1 genotype in group 3 gestational onset diabetes mellitus was 3.38, although this value did not reach statistical significance in this small sample ($\chi^2_{mh} = 2.26$, $p > 0.10$). The gene and genotype frequencies did not differ significantly among patients with gestational onset diabetes mellitus in groups 1, 2, or 4 compared with matched control subjects.

Of interest is that the increased prevalence of first-degree relatives with diabetes mellitus of patients with gestational onset diabetes mellitus is only evident among those patients with elevated fasting plasma glucose levels. Among patients with gestational onset di-

abetes mellitus with normal fasting plasma glucose levels ($n = 41$), the proportion of first-degree relatives with diabetes mellitus was not different from that of matched controls ($p > 0.80$), and was significantly lower than in patients with gestational onset diabetes mellitus with elevated fasting plasma glucose levels ($n = 46$, $p < 0.001$).

Comment

Our data continue to support observations of others that gestational onset diabetes mellitus is a heterogeneous disorder with respect to both phenotypic and genotypic characteristics.[2-4] Our observation of increased frequencies of the class 1 allele in nonoverweight patients with gestational onset diabetes mellitus with elevated fasting plasma glucose values suggests that this allele may contribute to the development of gestational onset diabetes mellitus in some women. It is of interest that the frequency of the class 1 allele and the 1,1 genotype in these women is comparable with the frequencies reported in type 1 diabetes mellitus.[13] Although our sample size is too small to draw definitive conclusions, the data suggest that these women may represent a subgroup of gestational onset diabetes mellitus with slowly evolving type 1 diabetes mellitus or with undiagnosed type 2 diabetes mellitus before pregnancy. It is tempting to speculate that these women will remain diabetic under nongravid conditions. Lack of associations with the hypervariable region genotypes in the other phenotypic subgroups of gestational onset diabetes mellitus suggests that women who demonstrate glucose intolerance only during pregnancy may represent a novel subgroup of patients with diabetes mellitus whose genetic profiles differ from type 1 and type 2 diabetes mellitus.

Genetic heterogeneity within gestational onset diabetes mellitus is further supported by the different patterns of family histories of diabetes mellitus among phenotypic subclasses of gestational onset diabetes mellitus. That a patient with gestational onset diabetes mellitus with normal fasting plasma glucose values does not show greater prevalences of diabetes mellitus among first-degree relatives as compared with controls raises the possibility that the etiology of gestational onset diabetes mellitus among these women may not be genetic. Alternatively, a gene conferring susceptibility to glucose intolerance only during pregnancy would have sex-limited expression. This gene could be transmitted

through phenotypically normal fathers. Furthermore, because most women with gestational onset diabetes mellitus are asymptomatic, gestational onset diabetes mellitus may not have been recognized in the mothers of our subjects. Thus the prevalence of affected relatives would not necessarily reflect the prevalence of the gestational onset diabetes mellitus susceptibility gene in family members. In either case, our data suggest that in most women the insulin gene hypervariable region does not confer susceptibility to abnormal glucose tolerance in pregnancy.

We thank Dr. Graeme Bell for providing the *phins*96 probe, laboratory expertise, and helpful comments.

Percutaneous umbilical transfusion in severe rhesus isoimmunization: Resolution of fetal hydrops

Michael L. Socol, M.D., Scott N. MacGregor, D.O., Bruce W. Pielet, M.D., Ralph K. Tamura, M.D., and Rudy E. Sabbagha, M.D.

Chicago, Illinois

The rhesus-sensitized fetus with the worst prognosis is one with early onset of hydropic changes. Percutaneous umbilical blood sampling now enables access to the fetal circulation and thereby allows more precise evaluation of fetal anemia and direct intravascular transfusion. A variation of this technique was used in three pregnancies complicated by fetal pericardial effusion, scalp edema, and abdominal ascites before 26 weeks' gestation. Twelve ultrasound-guided percutaneous transfusions of 30 to 85 ml packed red blood cells were administered into the umbilical cord at its placental insertion. In each fetus the hydropic changes completely resolved and pregnancy outcome was successful. Neither adjunctive therapy with digoxin or Lasix nor exchange transfusions were used. Percutaneous umbilical transfusions appear to have the potential to improve the prognosis for the severely isoimmunized fetus. (Am J Obstet Gynecol 1987;157:1369-75.)

Key words: Percutaneous umbilical transfusion, rhesus isoimmunization, fetal hydrops

The improved resolution of dynamic ultrasound imaging has enabled more precise antepartum fetal evaluation and treatment. For example, recent reports have described the technique of percutaneous umbilical blood sampling and its application for in utero diagnosis and therapy.[1-7] For the severely isoimmunized fetus, the ability to perform a direct intravascular transfusion would eliminate the erratic and incomplete absorption of red blood cells inherent with the traditional intraperitoneal approach. This percutaneous technique could also reduce the procedure-related fetal mortality observed with intraperitoneal transfusions[8] and would seem to be technically easier and less traumatic than either intrahepatic[3] or fetoscopically directed[9] intravascular transfusions. We describe three rhesus-sensitized pregnancies complicated by fetal hydrops before 26 weeks' gestation in which ultrasound-guided percutaneous umbilical transfusions led to the resolution of hydropic changes and successful outcomes. Percutaneous umbilical transfusions appear to have the capability to improve considerably the prognosis for the severely isoimmunized fetus.

Reprint requests: Michael L. Socol, M.D., 333 E. Superior St., Room 438, Chicago, IL 60611.

Transfusion technique

Before each procedure, intramuscular meperidine and diazepam plus local anesthesia were administered, but neither prophylactic antibiotics nor tocolytic drugs were used. The placental insertion of the umbilical cord was identified by both linear array and sector real-time ultrasound (General Electric RT 3600, Milwaukee, Wisconsin). A 22-gauge 5-inch (12.70 cm) disposable spinal needle (Becton Dickinson, Rutherford, New Jersey) was then directed to the umbilical cord insertion site (Fig. 1) by the use of a 5 MHz sector transducer with a detachable needle guide (Civco Industries, Kalona, Iowa). After needle tip placement (preferably into the umbilical vein), blood was aspirated for immediate hematocrit analysis as well as complete blood count, blood type and Rh factor, and Kleihauer-Betke test as deemed necessary. The transfusion volume needed to raise the hematocrit to 35% to 45% was calculated by the following formula[9]:

$$V_2 = \left(\frac{Hct_3 - Hct_1}{Hct_2}\right) \times EFW \times V_1$$

where V_1 is the fetoplacental blood volume (150 ml/kg),[10] V_2 is the transfusion volume (in milliliters), EFW is the estimated fetal weight (in kilograms), Hct_1 is the initial fetal hematocrit, Hct_2 is the donor hematocrit (approximately 85%), and Hct_3 is the desired fetal hematocrit. Type O, Rh-negative, cytomegalovirus antibody–negative, frozen, washed, packed red blood cells were transfused at a rate of 1 to 3 ml/min. Fetal blood was also sampled before the end of the procedure to assess the adequacy of therapy.

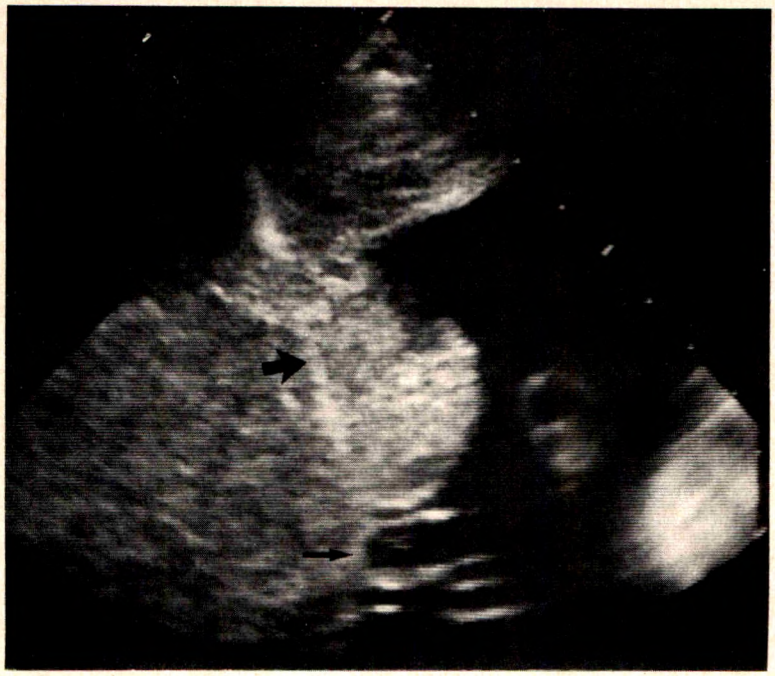

Fig. 1. The needle *(large arrow)* can be seen traversing the anterior placenta and entering the umbilical cord at its placental insertion *(small arrow)*.

After the transfusion, uterine contractions and fetal heart rate were monitored for at least 2 hours, after which the patient was discharged. Subsequent fetal surveillance consisted of ultrasound examinations and nonstress tests on at least a weekly basis, plus daily fetal movement counts.

The details of each case are presented below and summarized in Table I.

Case reports

Case 1. P. N., a 28-year-old, gravida 3, para 1-1-0-1, type A, Rh-negative, white woman, had a previous intrauterine fetal death at 34 weeks' gestation. At 19 weeks and 3 days of gestation of the index pregnancy, the indirect Coombs titer was 1:2048 and amniocentesis revealed the amniotic fluid delta optical density at 450 nm (ΔOD_{450}) to be 0.09. Amniocentesis was repeated at 21 weeks and 6 days, at which time the ΔOD_{450} was again 0.09. The patient was then referred to Prentice Women's Hospital, where at 23 weeks and 5 days the ultrasound examination suggested early fetal scalp edema, abdominal ascites, pericardial effusion, and hydramnios. The placenta was anterior and the umbilical cord insertion was clearly visualized in the lower portion of the placenta to the right of midline.

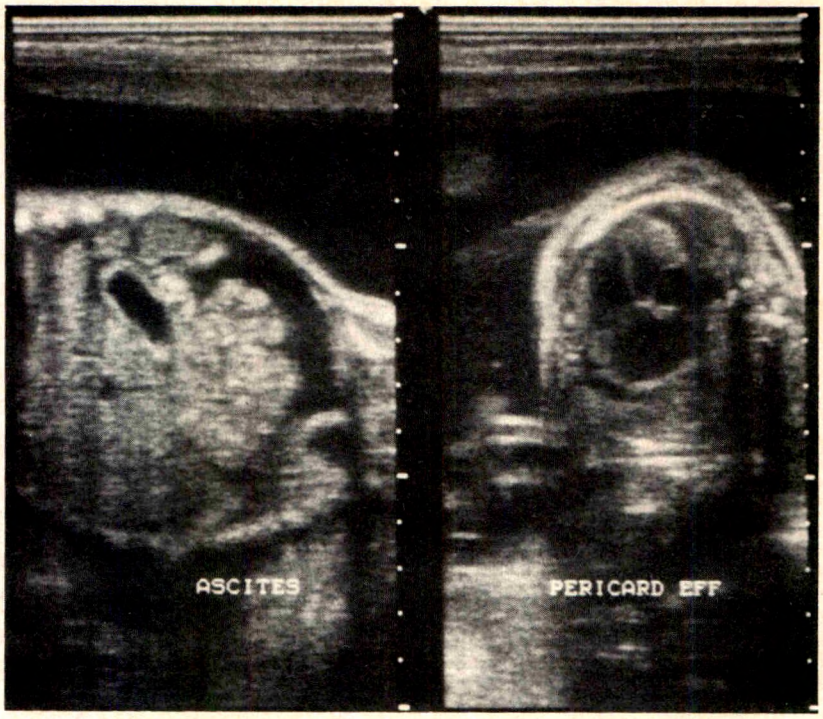

Fig. 2. Abdominal ascites *(left)* and pericardial effusion *(right)* are present at 24 weeks 6 days of gestation.

The initial fetal hematocrit was 24% and the transfusion volume needed to achieve a hematocrit of 35% to 45% was calculated to be 20 ml. After infusion of 18 ml of packed red blood cells, fetal movement dislodged the needle but replacement was not attempted because the calculated volume had nearly been transfused. However, the red blood cell indices and blood type were shortly thereafter reported as consistent with maternal blood (i.e., mean corpuscular volume of 89 fl, type A, Rh negative) and the Kleihauer-Betke test confirmed that the blood sample was maternal. As the patient was reluctant to repeat the procedure, she was monitored with daily fetal movement counts and twice-weekly ultrasound examinations. At 24 weeks and 6 days of gestation, ultrasound showed increased fetal hydrops (Fig. 2) and percutaneous umbilical blood sampling revealed a hematocrit of 13%. An intravascular fetal transfusion of 30 ml of packed red blood cells was performed, raising the hematocrit to 24%. Turbulence within the umbilical cord was visualized throughout the transfusion, assuring satisfactory needle placement. Also, the mean corpuscular volume of the aspirated blood was reported as 151 fl and the blood type was O, Rh positive, further confirming needle placement into an umbilical vessel. Although the final hematocrit was less than the desired end point, concern about possible volume overload led to termination of our initial transfusion. One week later fetal ascites had increased and a sinusoidal fetal heart rate pattern was noted. Intravascular transfusion was repeated, at which time the Kleihauer-Betke test revealed <1% fetal cells; 58 ml of packed red blood cells raised the fetal hematocrit from 8% to 31%. Fetal movement caused dislodgment of the needle twice during the transfusion, as evidenced by turbulence in the amniotic fluid rather than the umbilical vessel, and reinsertion of the needle was required. By the end of the transfusion the sinusoidal pattern had disappeared and fetal heart rate reactivity had improved. The following week, at 26 weeks and 6 days of gestation, ultrasound examination indicated that the hydramnios had resolved and that the fetal hydrops had improved. A third transfusion was performed, during which 55 ml of packed red blood cells raised the hematocrit from 24% to 40%.

Three days later, at 27 weeks and 2 days of gestation, the patient presented to labor and delivery in premature labor. Ultrasound demonstrated complete resolution of fetal hydrops. Tocolysis with intravenous ritodrine was attempted, but spontaneous rupture of the membranes occurred, followed by umbilical cord prolapse. A primary cesarean section was performed, with delivery of a 1080 gm female infant with Apgar scores of 2 and 7 at 1 and 5 minutes, respectively, and an umbilical artery pH of 7.29. The umbilical cord showed no evidence of trauma. A maternal urine toxicology screen was positive for phencyclidine, but the newborn urine screen was negative. The neonatal hematocrit was 37%, the white blood cell count was 6700/mm^3, the platelet count was 252,000/mm^3, and the Kleihauer-Betke test identified <1% fetal cells. The infant developed respiratory distress syndrome and remained intubated for 14 days but has since done well. Although

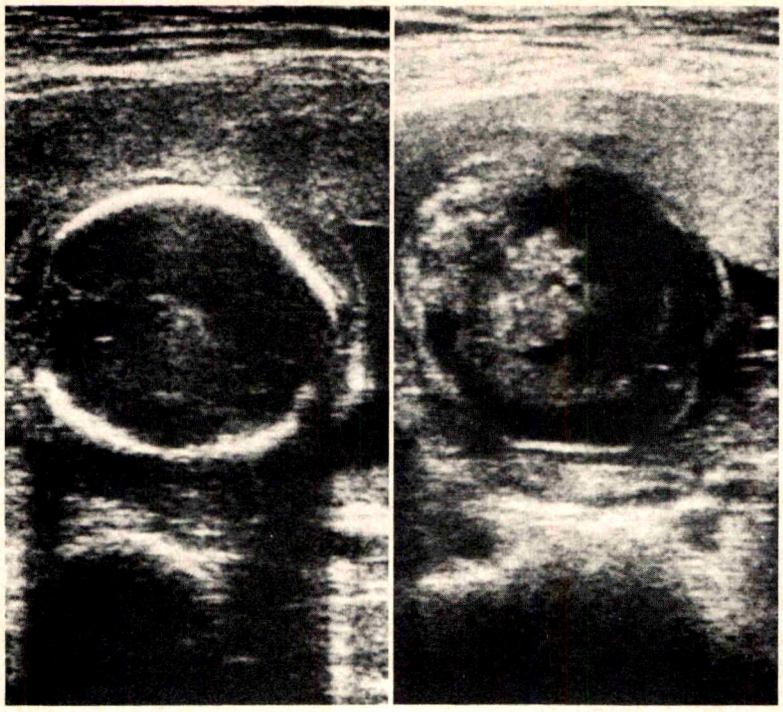

Fig. 3. Fetal scalp edema *(left)* and massive abdominal ascites *(right)* surrounding the liver and bowel are clearly visualized at 22 weeks 5 days of gestation.

exchange transfusions were not required, a total of 156 ml of packed red blood cells was transfused on 10 occasions during the 79-day hospitalization, principally to replace iatrogenic losses. On discharge the hematocrit was 25% and the reticulocyte count remained 0.0%. No outpatient transfusions were administered but the reticulocyte count did not rise to 0.5% until day 101 of life. By day 107 the reticulocyte count was 4.2%, with the peak being 10.1% on day 114.

Case 2. V. D., a 32-year-old, gravida 4, para 0-2-1-0, type O, Rh-negative, black woman, had a history of stillbirths at 36 weeks' and 26 weeks' gestation, the latter after an intraperitoneal fetal transfusion. During the current pregnancy the initial indirect Coombs titer was 1:64 and amniocentesis at 23 weeks 6 days of gestation identified the ΔOD_{450} to be 0.40. Ultrasound examination could not clearly identify the umbilical cord insertion into the anterior fundal placenta, and in view of the absence of fetal hydrops plus the circumstances of the last pregnancy loss, it was elected to delay the transfusion until the following week rather than perform an intraperitoneal procedure. At 24 weeks 6 days, percutaneous umbilical blood sampling was unscucessfully attempted, but with the continued absence of hydropic changes the patient was followed up with daily fetal movement counts and ultrasound evaluation twice weekly. At 25 weeks 6 days, ultrasound examination revealed mild scalp edema, ascites, and pericardial effusion. Percutaneous umbilical blood sampling was successful on the fourth attempt and was accomplished by traversing the placenta and amniotic cavity, thereby entering the umbilical cord 2 to 3 cm from the placental insertion. The fetal hematocrit of 14% was raised to 38% by the transfusion of 58 ml of packed red blood cells. Ultrasound examination during the next week indicated that the hydrops had resolved, but at 28 weeks 2 days of gestation mild hydropic changes recurred and hydramnios was present. The fetal hematocrit was only 10%, with <1% fetal cells, and was raised to 35% via the transfusion of 85 ml of packed red blood cells. At 29 weeks of gestation ultrasound demonstrated resolution of the fetal hydrops and hydramnios, but at 30 weeks 2 days the patient noted decreased fetal movement and the nonstress test, which had previously been reactive, was now considered borderline. A third intrauterine transfusion was therefore performed, at which time the pretransfusion hematocrit of 21% was raised to 43% by the infusion of 75 ml of packed red blood cells. Amniotic fluid was aspirated during the procedure and the lecithin/sphingomyelin ratio was later reported as 2.0 with phosphatidylglycerol present.

In view of the previous declines in fetal hematocrit during a 2-week interval and the mature lung profile, it was decided to deliver the fetus at 32 weeks 3 days of gestation. A 1700 gm male infant was delivered by primary cesarean section with Apgar scores of 7 and 8 at 1 and 5 minutes, respectively, and an umbilical artery pH of 7.32. The umbilical cord was centrally inserted into the placenta and demonstrated no evidence of trauma. The neonatal hematocrit was 39%, the white blood cell count was 5600/mm^3, the platelet count was 284,000/mm^3, and the Kleihauer-Betke test revealed

<1% fetal cells. The neonate was extubated within 24 hours, required no exchange transfusions, and has done well. Only two simple transfusions of 16 and 22 ml of packed red blood cells were administered during the 26-day hospitalization. At discharge the neonatal hematocrit was 42%, but by 8 weeks of age the hematocrit had dropped to 20% with the reticulocyte count still at 0.0%. An outpatient transfusion raised the hematocrit to 35%. Two weeks later the reticulocyte count was 1.8% and no further transfusions were required.

Case 3. R. G., a 38-year-old, gravida 3, para 2-0-0-2, type O, Rh-negative, white woman, was noted to be sensitized at the time of her first delivery, which was by cesarean section because of cephalopelvic disproportion. Her second delivery was by repeat cesarean section at 38 weeks' gestation; the umbilical cord hemoglobin and bilirubin levels were 11.5 gm/dl and 6.7 ng/dl, respectively, and the neonate required seven exchange transfusions. She was first seen at Prentice Women's Hospital at 9 weeks' gestation of the index pregnancy, at which time the indirect Coombs titer was 1:512. Thought was given to performing percutaneous umbilical blood sampling at 18 weeks for both rapid determination of karyotype and assessment of fetal hematocrit. However, it was felt that the risks of this relatively new procedure would be greater than those of genetic amniocentesis, particularly in a patient who had two previous term pregnancies and might not require intrauterine transfusion. Therefore genetic amniocentesis was performed at 15 weeks and revealed a normal karyotype and α-fetoprotein level. Unfortunately, at 22 weeks 5 days of gestation, ultrasonic examination identified fetal scalp edema and massive abdominal ascites (Fig. 3) without hydramnios. On the next day an ultrasound-guided intrauterine transfusion was performed, with the umbilical vein penetrated at its insertion into the anterior placenta. Forty-five milliliters of packed red blood cells raised the fetal hematocrit from 7% to 30%. One week later, at 23 weeks 6 days of gestation, minimal scalp edema and pericardial effusion were present but moderate abdominal ascites persisted. An attempt to repeat the intrauterine transfusion was unsuccessful, principally because the fetus was lying against the placenta at the site of the umbilical cord insertion. However, 2 days later, at 24 weeks 1 day, a repeat transfusion was performed without difficulty, during which 45 ml of packed red blood cells raised the fetal hematocrit from 25% to 50%; a Kleihauer-Betke test performed on the initial sample indicated <1% fetal cells. By 25 weeks' gestation all signs of fetal hydrops had resolved and a third transfusion of 32 ml of packed red blood cells at 26 weeks 6 days raised the fetal hematocrit from 31% to 45%. At 28 weeks 6 days the fetus was again lying against the umbilical cord insertion, but the fourth transfusion was easily performed by rotating the patient approximately 45 degrees onto her left side. Forty milliliters of packed red blood cells were infused and raised the fetal hematocrit from 31% to 44%. The fifth transfusion was performed at 30 weeks 6 days of gestation, with the initial fetal hematocrit being 32%. Forty-two milliliters of packed red blood cells were transfused, but on an attempt to obtain a posttransfusion blood sample the needle was displaced and could not be reinserted into the umbilical vein. Amniotic fluid was aspirated and yielded a lecithin/sphingomyelin ratio of 1.6 with phosphatidylglycerol absent. After the transfusion the baseline fetal heart rate declined from 140 to 110 bpm but the heart rate pattern remained reactive and the patient was allowed to go home. Two days later a nonstress test was reactive, with a baseline heart rate of 140 bpm. At 32 weeks 5 days, amniocentesis was performed, but the lecithin/sphingomyelin ratio was reported as 1.4 with phosphatidylglycerol absent. Consequently, a sixth transfusion was administered at 33 weeks 2 days of gestation and 40 ml of packed red blood cells raised the fetal hematocrit from 31% to 39%. Again there was a decrease in baseline fetal heart rate from 130 to 105 bpm, but by 2 hours the fetal heart rate returned to 130 bpm and the tracing was reactive.

At 35 weeks 5 days, the lecithin/sphingomyelin ratio was 3.0 with phosphatidylglycerol present. The next day a 2260 gm female infant was delivered by repeat cesarean section with Apgar scores of 7 and 9 at 1 and 5 minutes, respectively, and an umbilical artery pH of 7.30. The neonatal hematocrit was 31%, the white blood cell count was 12,900, the platelet count was 213,000, and the Kleihauer-Betke test indicated <1% fetal cells. The newborn infant was discharged with her mother on the fifth hospital day; the hematocrit was 33% and the reticulocyte count reported at <0.2%. On day 15 of life an outpatient transfusion of 50 ml of packed red blood cells was administered because the hematocrit was 21% and the reticulocyte count was <0.1%. On day 36, 30 ml of packed red blood cells were transfused because the hematocrit was 28%. By day 49 the hematocrit dropped to 23%, with the reticulocyte count persisting at <0.1%, but six days later the reticulocyte count increased to 5.5%, with a peak of 11.2% on day 59. No further transfusions were necessary.

Comment

Therapy for the fetus with severe rhesus isoimmunization is directed toward correction of the hemolytic anemia. In addition to eliminating the problem of incomplete absorption of blood and potentially decreasing the risks of fetal morbidity and mortality associated with intraperitoneal therapy, the percutaneous umbilical technique enables the fetal hematocrit to be determined during the transfusion. This maximizes the ability to raise the fetal hematocrit to the desired value and minimizes the possibility of either undertransfusion or overtransfusion. Even more basic to the management of the isoimmunized pregnancy, percutaneous umbil-

ical blood sampling can be used in conjunction with the Liley curves, particularly in the second trimester, to determine whether the optimal management is continued observation or intrauterine transfusion.[11]

Adjunctive therapy with furosemide, digoxin, or both has been recommended at the time of fetal transfusion.[9, 12] However, it is doubtful that the erythroblastosis is secondary to heart failure, because even the severely hydropic fetus does not appear to have increased intravascular volume.[13] More likely, the hydropic changes are related to the increase in portal pressure because of disordered hepatic parenchyma and the decrease in colloid osmotic pressure associated with hypoproteinemia secondary to liver dysfunction.[8] Chronic anemia may also be etiologically important, and it has recently been postulated that this may initiate the hydropic process via tissue hypoxia.[14] Consequently, furosemide may unnecessarily deplete the intravascular volume and digoxin will probably not be beneficial, because even if heart failure is present it likely will be high-output failure related to anemia.[14, 15] Correlation of the anemia and suppression of extramedullary hematopoiesis treat the underlying disease process, and in the three patients we report these procedures successfully reversed the hydropic changes. These observations would seemingly suggest that adjunctive therapy during intravascular transfusion is unnecessary.

The theoretical risk of cardiovascular compromise from fluid overload with simple transfusions as opposed to exchange transfusions has been raised.[6] However, in these three pregnancies the hydropic fetuses tolerated the simple transfusions of packed red blood cells in the volumes necessary to increase the fetal hematocrit above 35%. During the 12 transfusions, neither fetal tachycardia nor periodic decelerations were observed, and the fetal heart rate reactivity was either unchanged or improved after transfusion. The two instances in which the baseline heart rate declined from 130 to 140 down to 105 to 110 bpm probably reflected baroreceptor reflex activity, as the heart rate pattern remained reactive and the change was well tolerated by the fetus. Of note, this downward resetting of the fetal baseline heart rate occurred in the same fetus at the most advanced gestational ages at which it was transfused. A possible disadvantage of exchange transfusions is that the likelihood of needle displacement will be increased with prolongation of the procedure.

Successful transfusions with a free-hand technique with either sector or linear-array ultrasound have been previously described.[1, 6, 7] An advantage of the sector transducer with a detachable needle guide is that the needle is fixed in the sonographic plane and the needle tip can be continuously visualized during the puncture of the umbilical vessel and the subsequent transfusion. Placement of the needle in the umbilical vein is preferred because of its larger diameter and decreased propensity for vasospasm, but in one of the 12 transfusions the needle tip was in an umbilical artery. Most importantly, the observation of turbulence within the umbilical vessel during the transfusion ensures proper placement throughout the procedure. The 22-gauge disposable spinal needle is potentially more traumatic than the 25-gauge needle used in one series.[2] However, evidence of umbilical cord trauma was not observed at delivery and Daffos et al.,[1] using a 20-gauge needle, identified only one possible case of cord trauma and fetal death during fetal blood sampling in a series of 606 pregnancies. Disadvantages of the 25-gauge needle are that it is more flexible and more easily bent with maternal or physician movement. Further, the smaller gauge is more likely to cause lysis of cells at the time of transfusion or to become occluded. Finally, the blood was infused at a rate of 1 to 3 ml/min and a smaller bore needle would increase the time required for the procedure.

In summary, although the risks associated with percutaneous umbilical blood sampling and intravascular therapy remain to be quantified and issues pertaining to technique and timing of transfusion need to be resolved, the ability to gain access to the fetal circulation offers considerable promise in both antepartum diagnosis and treatment. In these three severely isoimmunized pregnancies, early onset fetal hydrops was reversed and successful outcomes were achieved. As previously cautioned,[16] this procedure requires considerable skill and precision and should be performed at centers with experience in fetal diagnosis and therapy.

Human fetal responses to vibratory acoustic stimulation from twenty-six weeks to term

Robert Gagnon, M.D., Cora Hunse, R.N., Lesley Carmichael, B.Sc., Fraser Fellows, M.D., and John Patrick, M.D.

London, Ontario, Canada

Eighty-three healthy pregnant women between 26 and 40 weeks' gestational age were studied to examine effects of a 5-second external vibratory acoustic stimulus on the fetal heart rate, fetal breathing, and gross fetal body movement patterns. There was an immediate fetal heart rate response, following stimulus, characterized by an increase in duration of fetal heart rate accelerations from 26 weeks to term with an increase in basal fetal heart rate after 30 weeks. There was also a delayed response after 33 weeks' gestation, which consisted of an increase in the number of fetal heart rate accelerations and the incidence of gross fetal body movements for up to 1 hour after a 5-second stimulus with the electronic artificial larynx. Term (36 to 40 weeks) fetuses made breathing movements more irregularly after vibratory acoustic stimulation. We suggest that human fetal responses to stimulation with the electronic artificial larynx may reflect a functional maturation of the fetal central nervous system. (AM J OBSTET GYNECOL 1987;157: 1375-81.)

Key words: Fetal responses to sound and vibration; antepartum fetal heart rate testing; effect of vibration on fetal movements

It has been demonstrated that external vibratory acoustic stimulation with an electronic artificial larynx reproducibly causes changes in the fetal heart rate (FHR)[1-3] and movement patterns[4] in term fetuses. It was proposed that FHR accelerations after stimulation with the EAL might reflect fetal health. Before introduction of this device as a clinical test, there is a need to document the effect of gestational age on the response.

The purpose of this study was to define, in a group of healthy fetuses from 26 weeks' gestational age to term, changes in fetal heart rate, fetal breathing, and gross body movements after a standardized external vibratory acoustic stimulus.

Patients and methods

Patients. Informed consent was obtained from 89 healthy pregnant women between 26 and 40 weeks' gestational age. Eighty-three women remained in good

health. Five women were delivered of their infants before 37 weeks: Two had abruptio placentae, two had premature labor, and one was delivered of a stillborn infant at 35 weeks'. The cause of death was unknown. Another patient was lost to follow-up. These six women were excluded from subsequent analysis. All other women had normal term deliveries that confirmed gestational age and the good health of the fetuses studied. The average gestational age at delivery was 39.3 ± 0.1 week (SEM). The average weight of the fetuses was 3350 ± 42 gm. The average 5-minute Apgar score was 9.3 ± 0.1. No Apgar score was <7 at 5 minutes. Umbilical cord blood arterial samples were obtained at birth in 58 of the 83 fetuses. The mean umbilical arterial P_{O_2} was 17.8 ± 1.0 mm Hg, the P_{CO_2} was 50.0 ± 1.3 mm Hg, and the pH was 7.27 ± 0.01. Ten (13.7%) women were delivered by cesarean section: Two developed acute fetal distress in labor (5-minute Apgar scores of 8 and 10, respectively), one had cephalopelvic disproportion, one had a transverse fetal lie at the onset of labor, and six had repeat cesarean sections. Eighty-one fetuses were in the vertex presentation and two were in breech positions at the time of delivery.

Experimental design. The women received a standardized 800 kcal breakfast or lunch at 8:00 AM (n = 48) or 12:00 noon (n = 53). All studies began 1 hour later and were conducted in a quiet room with the patients either sitting upright in bed or resting in a lateral recumbent position. Women were asked not to smoke for at least 4 hours before the studies. Smoking or food intake by patients or observers was not permitted during the studies.

All women had been acclimatized by listening to the stimulus in air before the beginning of studies and were informed that the stimulus might be applied either on the abdomen or the hand. Women were studied continuously for 2 hours. At the end of the first hour of observation, a 5-second vibratory acoustic stimulus was applied on the surface of the maternal abdomen over the fetal head (n = 51) or on the maternal hand (n = 50) for controls. The choice of whether to stimulate the abdomen or the hand of each woman was made from random number tables. Eight women in different gestational age groups had both control and stimulus, and studies in these women were separated by at least 2 days. All women received only one stimulus to either the abdomen or the hand during individual studies.

The external vibratory acoustic stimulus used in this study was generated with a Model 5C electronic artificial larynx (Western Electric, New York, New York, courtesy of Mr. John Kasper, Corometrics Medical Systems), as previously described.[1]

Fetal and maternal cardiovascular measurements. The FHR was recorded with a Hewlett Packard Model 8040A external monitor (Hewlett Packard GMBH, Boeblinger, Federal Republic of Germany) and a compact transducer and analyzed on line by a Stage II microprocessor (Sage Technology, Reno, Nevada) as previously described.[3] The fetal heartbeat intervals were examined with an artifact detection algorithm,[5] and valid pulse intervals were averaged over 3.75 seconds. During analysis, a baseline was fitted to the heart rate record[6] and accelerations of ≥10 bpm for ≥15 seconds above the baseline were recognized automatically.

For each 10-minute interval, the basal FHR (in beats per minute), the root mean square (in milliseconds), and the mean minute range (in milliseconds) were calculated. The root mean square and the mean minute range are numerical measurements of long-term FHR variability.[7] The maternal heart rate and the systolic, diastolic, and mean arterial blood pressures were automatically recorded every 5 minutes with a Dinamap (Model 845 XT, Critikon Inc., 1982, Tampa, Florida) and were not altered by vibratory acoustic stimulation.

Measurements of fetal activity. Fetal breathing movements and gross fetal body movements were measured with a real-time ADR ultrasound scanner (Model 2130, Advanced Diagnostic Research Corp., Tempe, Arizona) and analyzed on line in 5-minute intervals with a PDP 11/34 minicomputer as previously described.[8] The transducer operated at a frequency of 3.5 MHz with an average intensity of 0.045 mW/cm^2. Individual gross fetal body movements and fetal breathing movements were identified on a video monitor and coded with an event marker. The transducer was positioned over the maternal abdomen to permit continuous observation of a longitudinal cross section of fetal chest and abdominal wall echoes.[8]

Data analysis. The basal FHR, the number of FHR accelerations of ≥10 bpm for ≥15 seconds above the baseline, the duration and amplitude of individual FHR accelerations, the total time spent in acceleration, the root mean square, and the mean minute range values were determined for successive 10-minute intervals. Maternal heart rate and blood pressure were analyzed as means ± SEM for each 5-minute interval. All other results are presented as means ± SEM for successive 10-minute intervals before and after vibratory acoustic stimulus on the maternal abdomen or on the maternal hand (control) for the 2-hour observation periods. Portions or records that could not be analyzed because of FHR signal loss of more than 30% or patient interruption were not included. These portions made up 3.5% of total study time.

Measurements of the percentage of time spent mak-

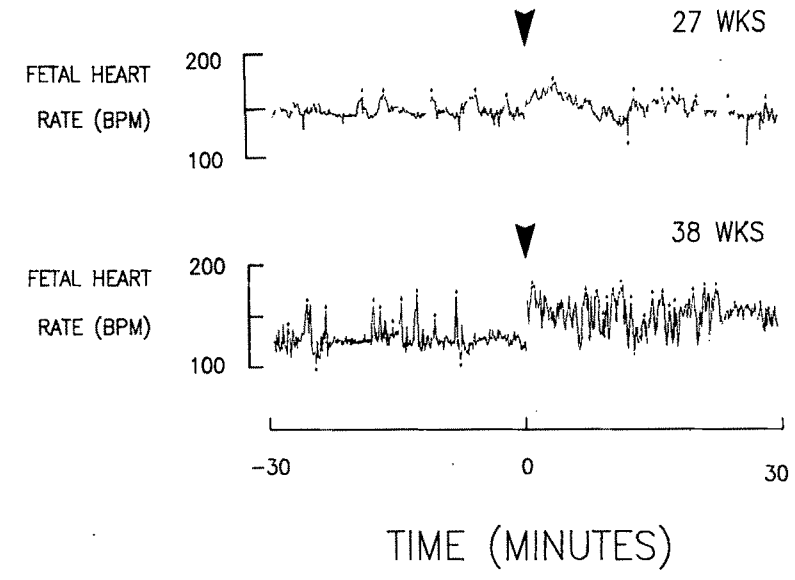

Fig. 1. Examples of an increase in FHR after a 5-second vibratory acoustic stimulus with the electronic artificial larynx in a 27-week fetus and in a 38-week fetus.

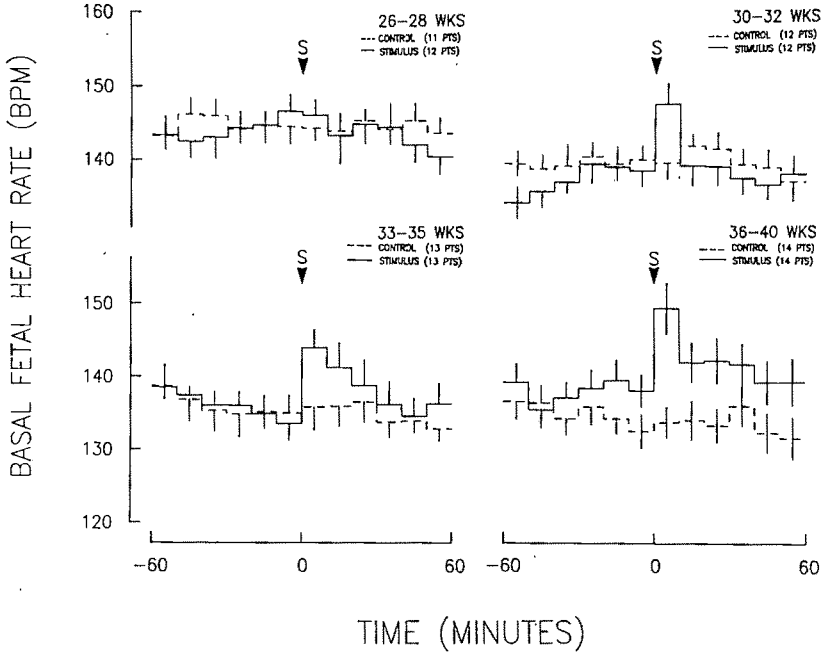

Fig. 2. The mean basal FHR (±SEM) was plotted for each group of fetuses at 26 to 28, 30 to 32, 33 to 35, and 36 to 40 weeks' gestation, in 10-minute intervals before and after control (– – –) or stimulus (———).

ing gross fetal body movements, the percentage of time spent making breathing movements, and the frequency distribution of breath-to-breath intervals were calculated for each 10-minute interval of the 202 hours of total observation time. Portions of movement records that could not be analyzed because of technical problems or patient interruption made up 2.7% of total time.

Statistical significance between groups before and after stimulus or control was determined by using a

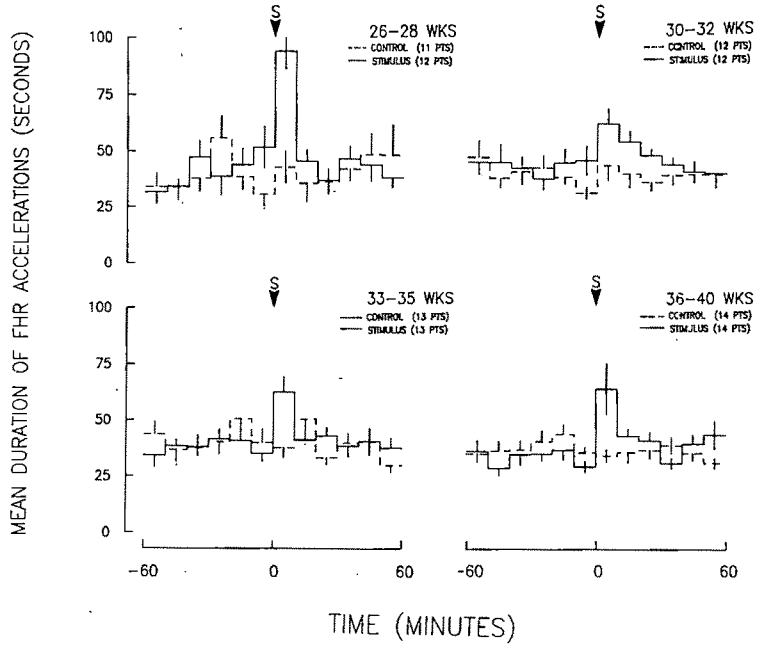

Fig. 3. The mean duration of FHR accelerations was plotted for each group of fetuses at 26 to 28, 30 to 32, 33 to 35, and 36 to 40 weeks' gestation, in 10-minute intervals before and after control (– – –) or stimulus (———).

mixed, nested analysis of variance comparing overall means and each of the 10-minute intervals[9] with an HP 9845B microprocessor (Hewlett Packard, Computer Division, Fort Collins, Colorado).

Results

FHR and FHR accelerations. Examples of the FHR response after vibratory acoustic stimulation with the electronic artificial larynx at 27 and 38 weeks are shown in Fig. 1. The mean basal FHR was 140.0 ± 1.9, 136.0 ± 1.4, and 138.4 ± 2.2 bpm at 30 to 32, 33 to 35, and 36 to 40 weeks of gestation, respectively, during the hour before stimulus. The mean basal FHR increased significantly to 148.0 ± 2.8, 144.0 ± 2.5, and 149.0 ± 2.3 bpm during the first 10 minutes after stimulus compared with control values (analysis of variance; $p < 0.001$, $p < 0.01$, $p < 0.001$, respectively) (Fig. 2). Basal FHR also remained above the control value for the hour after the stimulus in term (36 to 40 weeks) fetuses (Fig. 2). In the 26 to 28 weeks group of fetuses, the basal FHR was 144.4 ± 1.3 bpm before vibratory acoustic stimulation and did not change after either control or stimulus (Fig. 2).

Fig. 3 summarizes the mean duration of FHR accelerations per 10-minute interval from 26 to 40 weeks before and after stimulus or control. Analysis of variance demonstrated a significant increase in the mean duration of FHR accelerations at 26 to 28, 30 to 32, 33 to 35, and 36 to 40 weeks during the first 10 minutes after the stimulus (94 ± 5, 62 ± 6, 63 ± 7, and 64 ± 11 seconds, respectively) compared with control values (40 ± 6, 40 ± 6, 38 ± 3, and 35 ± 1 seconds) (analysis of variance; $p < 0.001$, $p < 0.01$, $p < 0.01$, and $p < 0.05$, respectively).

No significant change was found in computer-derived indexes of FHR variability at any gestational age after vibratory acoustic stimulation when compared with control values.

Relationship between gross fetal body movements and the number of FHR accelerations. There were 2.9 ± 0.2 and 2.5 ± 0.3 FHR accelerations per 10-minute interval at 33 to 35 and 36 to 40 weeks' gestational age during the hour before vibratory acoustic stimulation (Fig. 4, *A* and *C*). Analysis of variance demonstrated a significant increase in the number of FHR accelerations between 10 and 30 minutes at 33 to 35 weeks and between 10 and 20 minutes at 36 to 40 weeks ($p < 0.02$ and $p < 0.03$). It was important that all fetuses that received stimuli from 33 to 40 weeks exhibited FHR accelerations between 10 and 20 minutes after stimulation with the electronic artificial larynx (Fig. 4, *A* and *C*).

Similarly, there was a significant increase in the incidence of gross fetal body movements from 7.4% ± 0.9% and 5.8% ± 0.7% (33 to 35 and 36 to 40 weeks) during the hour before stimulus to 14.5% ± 2.8% and 13.8% ± 2.3% in the hour after stimulus with electronic artificial larynx (analysis of variance; $p < 0.01$ and $p < 0.001$, respectively) (Fig. 4, *B* and *D*). The maximum increase in the incidence of gross fetal body

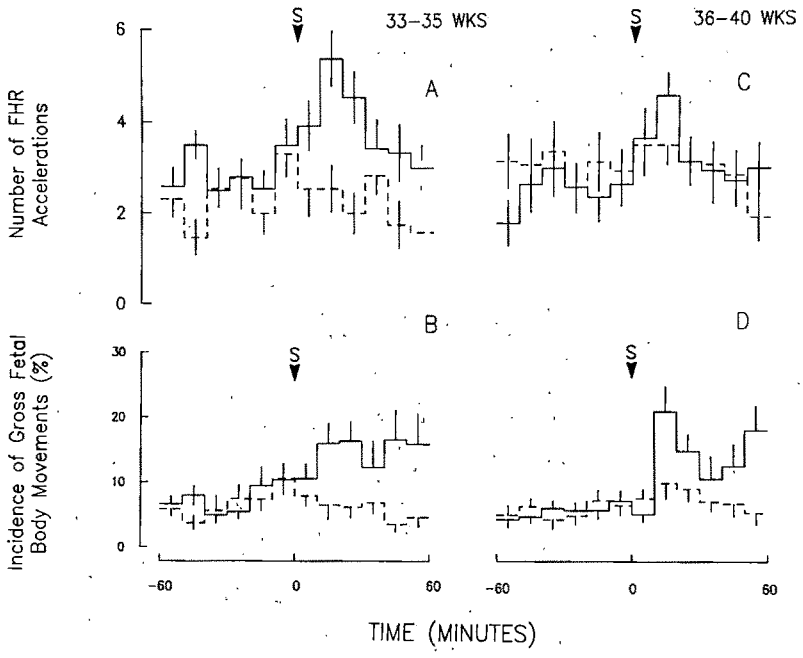

Fig. 4. The mean number of FHR accelerations was plotted in 10-minute intervals from 33 to 40 weeks before and after control (– – –) or stimulus (———). The mean incidence of gross fetal body movements was also plotted on the same time scale. There was a delayed increase in both number of FHR accelerations and the incidence of gross fetal body movements after vibratory acoustic stimulation.

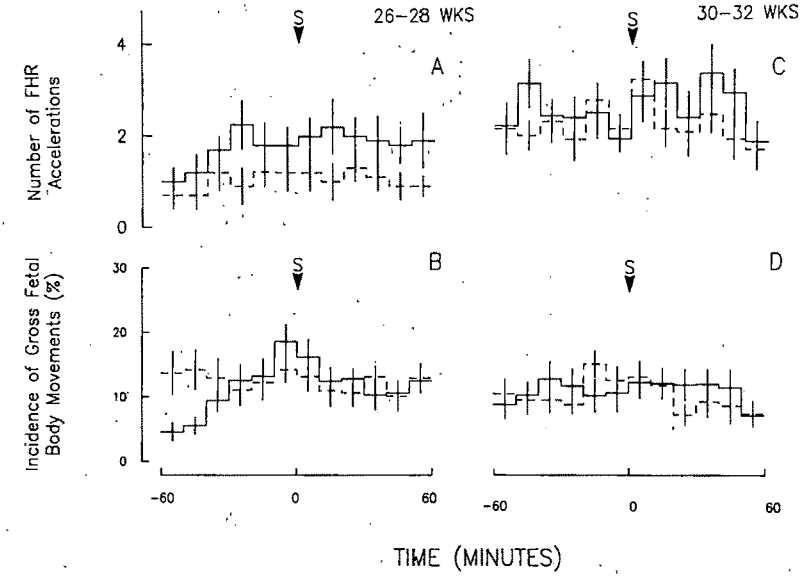

Fig. 5. The mean number of FHR accelerations was plotted in 10-minute intervals from 26 to 32 weeks before and after control (– – –) or stimulus (———). The mean incidence of gross fetal body movements was also plotted on the same time scale.

movements occurred between 10 and 30 minutes after the 5-second stimulus in both groups and did not return to control values for 30 to 60 minutes. The peak in the number of FHR accelerations coincided with the peak in the incidence of gross fetal body movements. Neither the number of FHR accelerations nor the incidence of gross fetal body movements increased until 10 minutes after the 5-second stimulus (Fig. 4, *A* to *D*). The number of FHR accelerations and the incidence of gross fetal body movements did not change significantly after

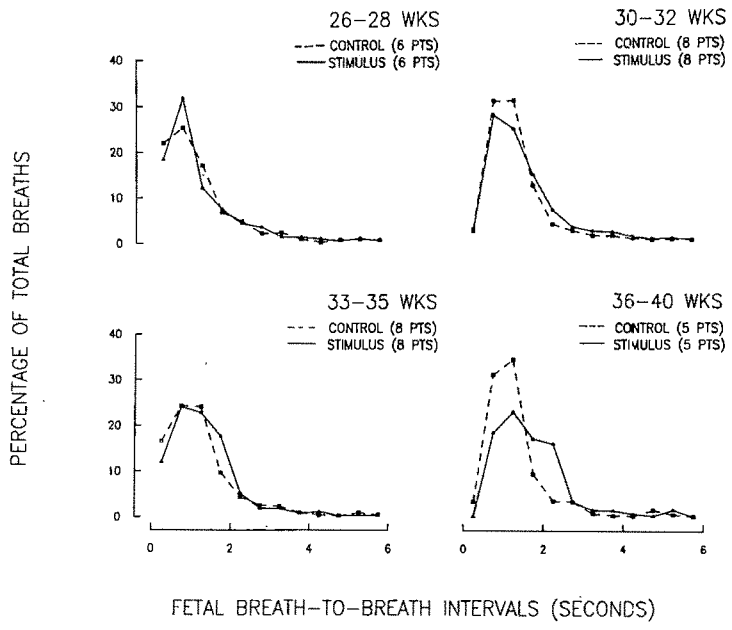

Fig. 6. Fetal breath-to-breath intervals were measured, and the histograms of the mean percentage of total breath-to-breath intervals in 0.5-second increments were plotted for 54 fetuses after stimulus (———) or control (– – –). There was a broad distribution of breath-to-breath intervals at 1.0 to 2.5 seconds without a well-defined peak after 36 weeks' gestation.

stimulus or control at 26 to 28 and 30 to 32 weeks' gestation (Fig. 5, *A* to *D*).

Fetal breathing movements. Term (36 to 40 weeks) fetuses made breathing movements 37.4% ± 5.2% of the time before the stimulus and decreased significantly to 15.7% ± 5.4% during the hour after stimulation with the electronic artificial larynx as compared with control values (31.4% ± 5.1%) (analysis of variance, $p < 0.05$). The incidence of fetal breathing movements was 17.1% ± 4.2%, 34.2% ± 5.1%, and 34.5% ± 5.2% during the hour before stimulus at 26 to 28, 30 to 32, and 33 to 35 weeks, respectively, and was not significantly altered by stimulus when compared with control.

Fig. 6 demonstrated histogram plots of the mean percentage of total breath-to-breath intervals in successive 0.5-second increments in 54 fetuses during the hour after control (n = 27) or stimulus (n = 27) between 26 and 40 weeks. At 36 to 40 weeks, there was a skewed distribution of breath-to-breath intervals with a peak of 1.0 to 1.5 seconds during the hour after control, but during the hour after stimulus, there was a broad distribution of breath-to-breath intervals at 1.0 to 2.5 seconds without a well-defined peak (Fig. 6). This suggested that term (36 to 40 weeks) fetuses were breathing more irregularly after vibratory acoustic stimulation. No such change in breath-to-breath intervals was found before 36 weeks' gestational age (Fig. 6).

Comment

The data demonstrated that, in a group of highly selected healthy fetuses from 26 to 40 weeks, human fetal responses to vibratory acoustic stimulation were significantly altered by gestational age. There was an immediate FHR response characterized by an increase in duration of FHR accelerations from 26 weeks to term with an increase in basal FHR after 30 weeks. There was also a delayed response after 33 weeks' gestation, which consisted of (1) an increase in the number of FHR accelerations and (2) an increase in the incidence of gross fetal body movements for up to 1 hour after application of a 5-second stimulation with the electronic artificial larynx. In term fetuses, there was an immediate decrease in the incidence of fetal breathing movements with a more irregular breathing pattern that persisted for 1 hour after stimulus.

An increase in FHR after external vibratory acoustic stimulation with a loudspeaker generating a white noise at 110 dB in an anencephalic fetus has been previously reported.[10] This suggested that the origin of the immediate FHR response after vibratory acoustic stimulation is subcortical rather than coming from the cerebral cortex. In this study, four healthy fetuses did not respond to this stimulus: two at 26 weeks', one at 27 weeks', and one at 30 weeks' gestation. However, a consistent FHR response was obtained after 30 weeks. This supported the concept that the immediate increase

in basal FHR and duration of FHR accelerations after stimulation with the electronic artificial larynx might be related to functional maturation of the fetal autonomic nervous system, which is believed to occur during a critical and narrow period between 28 to 30 weeks' gestational age.[11]

The delayed increase in the number of FHR accelerations with an increase in the incidence of gross fetal body movements after the 5-second stimulus, which occurred after 33 weeks' gestation, was very similar to the wakefulness state described by Prechtl et al.[12] in newborn humans at 34 to 36 weeks and by Nijhuis et al.[13] in human fetuses after 36 weeks. The irregular breathing pattern seen after stimulus at >36 weeks' gestation could also reflect a state of wakefulness.[12]

Smith et al.[14] recently reported that 47% of fetuses did not have any FHR accelerations after stimulation with the electronic artificial larynx during labor with normal scalp pH values compared with 9% during antepartum FHR testing.[2] These results supported the hypothesis that the immediate FHR response after vibratory acoustic stimulation might be markedly attenuated during labor and after rupture of the membranes because of impairment of transmission of the vibrational component produced by the electronic artificial larynx.[1]

Meissner's corpuscles, which transmit cutaneous vibratory tactile sensation, with a fundamental frequency response of 80 Hz, have been anatomically identified between 24 and 28 weeks in human fetuses.[15] Leader et al.,[16] using a vibratory tactile stimulus with a fundamental frequency of 98 Hz, were able to elicit a fetal "startle reflex" as early as 24 weeks' gestation. The spectrum analysis of sound and vibration produced by the electronic artificial larynx demonstrated a sound pressure level of 95 dB at 100 Hz and an amplitude of vibration of 43 dB at 100 Hz.[1] It is therefore possible that sound and vibration produced by the electronic artificial larynx at low frequencies (≤100 Hz) are enhanced with transmission through the uterine wall as reported in sheep[17] and stimulated vibratory tactile Meissner's corpuscles. Whether this mechanism could explain significant changes in rest-activity cycles in human fetuses after stimulation with the electronic artificial larynx remains speculative. However, stimulation of Meissner's corpuscles rather than acoustic stimulation could explain the 47% of false positive stimulation tests with the electronic artificial larynx during labor[14] and the lack of any correlation between congenital deafness and the FHR response to vibratory tactile stimulation.[10]

The results indicated that human fetal responses after vibratory acoustic stimulation were altered by gestational age. We suggest that these changes reflect a functional maturation of the fetal central nervous system and are mediated by vibrational pathways. It will be important to determine if fetal responses after stimulation with the electronic artificial larynx can be altered in compromised sick fetuses or in fetuses with subsequent developmental delay.

We wish to thank Professor G. S. Dawes and Mr. Isaac Rapoport for their interest in this work.

Fetal auditory brain stem response: Effect of increasing stimulus rate during functional auditory development

Mark A. Plessinger, M.S., and James R. Woods, Jr., M.D.
Cincinnati, Ohio

The fetal auditory brain stem response to increasing stimulus rates of 16, 32, 45, 64, 87, and 100 clicks/sec were determined in eight fetal lambs of 115 to 136 days' gestation (term = 145 days). To conduct these studies, a hysterotomy was performed on the pregnant ewe at 110 to 118 days' gestation to implant stainless steel electrodes in the fetal scalp and a hearing aid receiver in the fetal external ear canal. The fetus was returned to the uterus and the pregnancy was allowed to continue. Auditory brain stem responses from younger fetuses (115 to 125 days' gestation) were present at the slower click rates but were not observed consistently at the fast click rates until the fetuses were older (125 to 136 day's gestation). Latency values of the auditory brain stem response peaks decreased with increasing fetal age and increased with increasing stimulus rates. From a two-way analysis of variance, the influence of age and click rate alone and more important, the interaction of age and click rate were determined to have highly significant effects ($p < 0.001$) on latency values of wave I, wave V, and central conduction time. These auditory brain stem response results suggest that the cochlear component of the fetal auditory system undergoes rapid change in late gestation to process incoming stimuli at a faster rate. (AM J OBSTET GYNECOL 1987;157:1382-7.)

Key words: Fetal auditory brain stem response, click rate, auditory development, fetal sheep

Previous reports from our laboratory have demonstrated that the fetal auditory brain stem response can be measured in utero in the chronically instrumented fetal lamb during the final weeks of pregnancy.[1-3] These reports indicate that (1) the fetus responds neuroelectrically to sound, (2) auditory function in the fetal lamb begins at 115 to 120 days' gestation, and (3) developmental changes in auditory function can be monitored during the final weeks of pregnancy. This fetal animal model may have applications in testing the effects of a variety of perinatal conditions such as hypoxia, acidosis, infection, and exposure to drugs on the developing fetal auditory system.

Congenital hearing loss has been associated with a variety of causes including maternal infection,[4] prematurity,[5] acidosis,[5] and anoxia.[6] The perinatal history of an infant or young child with congenital hearing loss is often examined to identify adverse perinatal events as the causative agent for the hearing loss. Newborn hearing loss is linked by association to adverse perinatal events, since no animal model has been available to test adequately perinatal causes of congenital hearing loss. Defining normal auditory development in the chronically instrumented fetal sheep model may indicate critical periods of fetal growth in which the auditory system is vulnerable to perinatal insults.

In the present study, we examined the effects of increasing stimulus rate on the auditory brain stem response of the developing fetal lamb. The purposes of this study were as follows: (1) to determine if the immature auditory system of the fetus responds to a range of stimulus rates, (2) to determine whether the fetal auditory brain stem response exhibits latency changes with increasing stimulus rates, and if so, (3) to determine the influence of fetal age on the latency response of the auditory brain stem response to increasing stimulus rates. The results of this study provide new information on the development of auditory function in the fetus during the final weeks of pregnancy and define critical periods of auditory development, during which time adverse perinatal conditions may contribute to congenital hearing loss.

Methods

Fetal instrumentation. Eight fetal lambs (three from twin pregnancies and five singletons) were instrumented at 110 to 118 days' gestation (term = 145 days) for measurement of fetal auditory brain stem responses. After each pregnant ewe was administered spinal block anesthetic (tetracaine hydrochloride), a sterile midline abdominal incision was made to expose

the uterus. The left side of the fetal neck was marsupialized through a small uterine incision for catheterization of the fetal carotid artery. All fetal surgery was conducted after local injection of subdermal anesthetic (lidocaine [Xylocaine, 2%]). A catheter was placed into the lumen of the fetal carotid artery and passed to the level of the ascending aorta. After the neck incision was closed, the fetal head was maneuvered to the uterine incision. Stainless steel wires insulated with Teflon and encased in polyvinyl tubing were secured subdermally at the vertex and anterior to the right pinnae of the fetal head. These wires were used as the active and reference electroencephalographic electrodes, respectively. A Danavox Model CN (68 ohm) hearing aid receiver, which was covered with a condom, was secured in the fetal external ear canal ipsilateral to the reference electrode and contralateral to the side of the fetal carotid artery catheter. After fetal instrumentation was complete, the fetal head was returned to the uterus and the uterine and abdominal incisions were closed. The earphone leads, stainless steel wires, and arterial catheter were brought out the abdominal incision and passed through a subdermal tunnel to a pouch on the flank of the ewe.

Auditory brain stem response testing. Fetal auditory brain stem responses were obtained in response to a series of clicks produced by the Danavox earphone secured in the fetal ear. Each click represented a square wave pulse of 0.1 msec duration and of alternating pulse polarity. The stimulus intensity used in this study was 105 dB sound pressure level when measured in a 6 cc coupler of a sound level meter (Model 452, Scotts Instruments Laboratory) in the fast mode and with the linear scale.

The responses from 1200-click stimuli were amplified 10^6 times and averaged by a Synap I signal averaging computer (Infant Hearing Assessment Foundation, San Francisco, Calif.) with a 200 to 2500 Hz bandpass and a 50 μsec sampling interval. The final averaged response was plotted on heat-sensitive paper with a 10 msec grid. All auditory brain stem response tests were conducted in duplicate to ensure reproducibility between recordings. A wave deflection was considered reproducible when the latency varied by no more than 0.2 msec between auditory brain stem response recordings at the same click rate.

Testing for fetal auditory brain stem responses was begun the day after surgery. If auditory brain stem responses were obtained at the initial click rate of 16 clicks/sec, the auditory brain stem response tests were repeated at increasing click rates of 32, 45, and 64 clicks/sec to determine the maximal click rate that would elicit an auditory brain stem response. If fetal auditory brain stem responses were reproducible up to 64 clicks/sec, tests at 87 and 100 clicks/sec were also conducted. The animals were randomly retested at intervals of 1 to 8 days. Twice weekly, blood samples (0.5 ml) were withdrawn from the fetal arterial catheter for blood gas determination by a 1.0 ml heparinized glass syringe. The fetal arterial sample was analyzed for pH, P_{CO_2}, and P_{O_2} levels with a BMS-3 Radiometer blood gas analyzer adjusted to 39° C (normal sheep core temperature).

Qualitative and quantitative analyses were conducted on the data as follows: The reproducible auditory brain stem response to the highest click rate was determined for each animal for each testing day. This qualitative determination was conducted by visual inspection of the auditory brain stem response tracings for (1) reproducibility between individual tracings for each click rate and (2) similarity in wave pattern to auditory brain stem response tracings obtained at lower click rates. Linear regression was performed on this data to determine the rate of transition of responsiveness from slow click rates to fast click rates with increasing age.

Latency determinations were made only during testing sessions in which auditory brain stem response recordings were obtained at all six click rates (16, 32, 45, 87, and 100 clicks/sec). This approach was used to eliminate bias from latency measurements of auditory brain stem response of earlier age fetuses who exhibited auditory brain stem responses only at the lower click rates. The latency interval, in milliseconds, from the click stimulus to the first wave deflection (wave I) was determined as a measure of the peripheral auditory response. Latency measurements were also obtained from the click stimulus to wave V. The I-V interwave latency interval (central conduction time) was taken as a measure of the transmission time through the auditory tracts and nuclei within the brain stem and midbrain.

A two-way analysis of variance with repeated measures was performed on the latency data to determine age and click rate effects and the interaction effects on auditory brain stem response peak latencies and central conduction time values.

Results

All fetal lambs were healthy during the study. Analysis of fetal arterial blood samples for blood gas determinations was as follows: pH = 7.34 ± 0.11; P_{CO_2} = 34.5 ± 5.7 mm Hg; P_{O_2} = 23.0 ± 3.7 mm Hg (data presented as mean ± 1 standard deviation).

Auditory brain stem responses were initially recorded at 16 clicks/sec from all fetuses between 115 and 124 days' gestation. As previously reported from our laboratory, these initial auditory brain stem responses consisted of a five-wave complex of small reproducible deflections that increased in resolution as

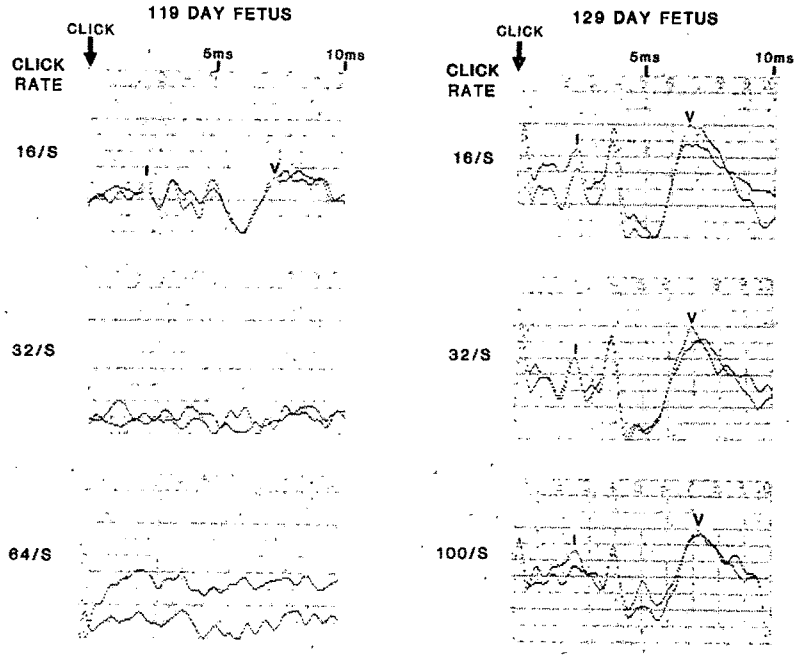

Fig. 1. Typical fetal auditory brain stem responses to increasing click rates at two different gestational ages.

the fetuses matured. Fig. 1 illustrates responses to click rates of 16, 32, and 64 clicks/sec from a 119-day fetus and responses to click rates of 16, 32, and 100 clicks/sec from a 129-day fetus. In this example, auditory brain stem responses were obtained at the lower click rate of 16 clicks/sec but not at 32 or 64 clicks/sec in the 119-day fetus. In the 129-day fetus, auditory brain stem responses were recorded up to 100 clicks/sec.

The extent of auditory brain stem response testing in all eight fetuses is graphically represented in Fig. 2. This figure indicates the gestational age of the fetal lambs at the time of surgery, the maximum click rate at which an auditory brain stem response could be obtained on a given day of testing, and the days of auditory brain stem response testing conducted on all eight fetuses. The lines connecting data points illustrate the progression of auditory brain stem response and click rate responsiveness in each individual fetus. Best-fit linear regression analysis of the progression of click rate responsiveness from 16 to 100 clicks/sec indicated a slope value of +14.2 click rate per gestational day. Once auditory brain stem responses were measured at 100 clicks/sec in each fetus, subsequent testing during the remainder of the testing period demonstrated continued auditory brain stem reponsiveness to all click rates up to 100 clicks/sec. Two ewes contracted pneumonia and died at 121 and 125 days. Fetal health in these two ewes as judged by the normal fetal blood gas and pH values was not compromised during the periods of fetal auditory brain stem response testing. The remaining six fetuses spontaneously delivered between 135 and 138 days' gestation, but died in the process of birth, presumably from the restraint of the fetal instrumentation.

Latency values for wave I, wave V, and the I-V interpeak values (central conduction time) are presented in Table I for each click rate at two gestational age groups of 117 to 126 and 129 to 136 days. All wave deflections used in the latency determinations were reproducible between auditory brain stem response tests, since none varied by any more than 0.2 msec at the same click rate. The data were divided into two groups to illustrate the effects of age and click rate on the auditory brain stem response latencies and central conduction time values. Comparisons of wave I, wave V, and central conduction time latency values in the two fetal age groups indicate decreasing latency values with increasing fetal age.

Two-way analysis of variance with repeated measures was conducted on the entire data set (not each age group separately). Two-way analysis of variance indicated significant effects of age on the latencies of wave I, wave V, and central conduction time values (wave I: $F = 393.6$, $df = 10$, $p < 0.001$; wave V: $F = 206.5$, $df = 10$, $p < 0.001$; central conduction time: $F = 45.3$, $df = 10$, $p < 0.001$). Two-way analysis of variance also indicated significant effects of click rate on the latencies of wave I, wave V, and central conduction time values (wave I: $F = 26.2$, $df = 5$,

$p < 0.001$; wave V: $F = 45.5$, $df = 5$, $p < 0.001$; central conduction time: $F = 19.8$, $df = 5$, $p < 0.001$). The interaction of age and click rate from the two-way analysis of variance indicated significant interactions on wave I latency: $F = 7.4$, $df = 50$, $p < 0.001$; wave V latency: $F = 5.1$, $df = 50$, $p < 0.001$; and central conduction time values: $F = 4.7$, $df = 50$, $p < 0.001$.

Comment

In the present study, we determined changes in characteristics of the auditory brain stem response to different stimulus rates in the chronically instrumented fetal lamb. This objective was accomplished by measuring auditory brain stem responses in utero at click rates of 16, 32, 45, 64, 87, and 100 clicks/sec during the final 26 days of gestation. Results obtained from earlier age fetuses indicate that auditory brain stem responses are initially measurable only at slow click rates. Once these initial auditory brain stem responses appear, subsequent auditory brain stem responses in response to click rates up to 100 clicks/sec are measurable over the next 3 to 10 days.

Fetal auditory brain stem response latencies to wave I, wave V, and central conduction time in the present study decreased as a function of gestational age. Results of auditory brain stem response studies in in-

fants, children, and adults have also demonstrated latency changes in auditory brain stem response peaks because of age and rate of stimulus presentation. From infancy to early adulthood, auditory brain stem response latencies decrease with increasing age.[7-9] These latency decreases are thought to represent increased myelination and synaptogenesis occurring in the brain stem and midbrain.[7, 10, 11] Fetal auditory brain stem response latencies also increased with increasing rates of stimulus presentation. Similar findings have been reported in human newborns and adults.[8, 9, 12, 13] The effects of click rate on auditory brain stem response latencies have been attributed by Don et al.[12] primarily to receptor adaptation and fatigue. However, Pratt and Sohmer[13] and Pratt et al.[14] have suggested that the latency increase of the auditory brain stem response is caused by reduced synaptic efficacy; that each successive wave of the ABR is influenced by the preceding wave. As such, when the click rate is increased, a smaller number of incoming fibers are active and their synapses are less effective. As a result, it takes longer for the excitory synaptic potential to reach the firing threshold for the outgoing fibers and hence the longer auditory brain stem response latencies at the higher click rates. This hypothesis also suggests that each successive wave exhibits a greater change in latency with increasing click rate when compared with the preceding wave(s).

The presence of auditory brain stem responses at various click rates in this study appears to be an all-or-none phenomenon. From the tracings in which auditory brain stem responses were not measurable at the faster click rates (115- to 125-day fetuses), there were no reproducible peaks in these tracings (Fig. 1). The use of alternating polarity clicks presented at high stimulus rates of 80+ clicks/sec may sometimes result in complete cancellation of wave I. Click polarity (rarefaction, condensation, or alternating), however, has no effect on the presence of or differences in latency values of wave V.[15] Although alternating polarity clicks were used in the present study, wave I was easily identifiable and reproducible at the higher click rates when auditory brain stem responses were present (Fig. 1). The absence of wave V and all other preceding auditory brain stem response peaks in the younger fetuses at the higher click rates suggests that the other auditory brain stem response peaks are dependent on the ability of the peripheral auditory apparatus to recover from high stimulus rates to properly conduct impulses. Therefore maturation must occur in the peripheral auditory apparatus (cochlea) as the fetus becomes older to integrate incoming auditory signals into the brain stem more effectively. Similar observations have been reported in a study of premature human infants in which auditory brain stem responses were obtained at a range of stimulus rates. Despland and Galambos[9] reported one infant at 30 weeks who did not have a wave V response to stimulus rates above 40 clicks/sec. Within 2 weeks, however, wave V responses were obtained at rates as high as 80 clicks/sec.

The results of the present study indicate that rapid change in auditory click rate responsiveness occurs in the fetal lamb from 115 to 125 days' gestation. This period of rapid change may be indicative of a time window in which critical auditory changes occur. Since the immature nervous system is most vulnerable to toxic damage when growth is rapid,[16] the peripheral auditory system may be especially vulnerable during this period of development. Despland and Galambos[9] observed that the highest incidence of hearing impairments occurred in premature infants who were acidotic at birth. Therefore it is reasonable to speculate that toxic damage from an abnormal perinatal event such as acidosis during this period of rapid change in auditory function may potentiate the risk of hearing impairment. The fetal model presented in this study offers a unique opportunity to test a variety of perinatal conditions during specific periods of fetal auditory development.

We thank the Infant Hearing Assessment Foundation, San Francisco, Calif., for providing the Synap I Signal Averaging Computer used in this study.

Pituitary responses to synthetic corticotropin-releasing hormone: Absence of modulatory effects by estrogen and progestin

J. H. Liu, M.D., D. D. Rasmussen, Ph.D.,* J. Rivier, Ph.D., W. Vale, Ph.D., and S. S. C. Yen, M.D., D.Sc.

La Jolla, California

To determine if the activity of the adrenocorticotropic hormonal–adrenal axis is modulated in part by estrogens and progestins, we have compared pituitary and adrenal responses to corticotrophin-releasing hormone in normal women during the early follicular, late follicular, and midluteal phases of the menstrual cycle and in four women undergoing ovariectomy who received estradiol (E_2) implants alone or in combination with oral medroxyprogesterone acetate administration. Basal adrenocorticotropic hormone and cortisol levels (9:00 AM) and responses to ovine CRH were unaffected by variations in E_2 and progesterone during each phase of the menstrual cycle. In women undergoing ovariectomy who received E_2 replacement therapy, basal concentrations of adrenocorticotropic hormone and cortisol (9:00 AM) and the responses to human corticotrophin-releasing hormone were not altered by administration of E_2 alone or E_2 with medroxyprogesterone acetate. Under these experimental conditions, our findings suggest that physiologic changes in E_2 and progesterone levels during the menstrual cycle and replacement doses of estrogen and progestin commonly used clinically do not significantly influence basal adrenocorticotropic hormone and cortisol levels or responsiveness to corticotrophin-releasing hormone. (AM J OBSTET GYNECOL 1987;157:1387-91.)

Key words: Adrenocorticotropic hormone, corticotrophin-releasing hormone, medroxyprogesterone acetate, estrogen, progestin

Although it is widely recognized that there is an increase in the onset of depressive syndromes[1] and aberrant psychologic behavior[2] during the premenstrual phase of the menstrual cycle, the role of ovarian steroids in these disorders remains unclear. Since the pituitary-adrenal axis has been implicated as a major neuroendocrine modulator of psychologic behavior and stress responses,[3] preliminary studies have focused on peripheral measurements of adrenocorticotropic hormone (ACTH) and cortisol output. These studies suggest that in normal women, basal levels of ACTH and cortisol are elevated during the late follicular and midcycle phases of the menstrual cycle,[4] whereas in the presence of high progestin levels, basal cortisol concentrations have been reported to decrease.[5] On the other hand, other investigators have reported that there is an enhanced adrenocortical responsiveness to

stress during the luteal phase of the cycle.[6] In view of these disparate findings, it seems necessary to examine first the modulatory role of ovarian steroids in ACTH-cortisol secretion at the pituitary and adrenal levels. To investigate these interactions, we have determined the pituitary and adrenal responses to corticotropin-releasing hormone in normal women during the menstrual cycle and in women underoing ovariectomy receiving hormone replacement therapy.

Material and methods

Six normal women between the ages of 26 and 43 years, with menstrual cycles between 28 and 32 days in length, volunteered for this study. Four women undergoing ovariectomy between the ages of 40 and 60 years were also studied. Each woman was within 10% of her ideal body weight.

In each experiment, subjects were admitted to the Clinical Research Center at 8:00 AM after an overnight fast. One hour after intravenous catheter placement, blood samples were collected at −20, 0, 20, 40, 60, 80, 100, 120, 150, and 180 minutes relative to the injection of corticotrophin-releasing hormone. Each woman with a normal cycle received either saline solution or ovine corticotrophin-releasing hormone, (1 μg/kg, intravenous bolus) during the early follicular phase (days 1 through 5) of the first menstrual cycle. During subsequent menstrual cycles, ovine corticotrophin-releasing hormone was administered during the late follicular (days 11 to 14) and midluteal (6 to 8 days after ovulation) phases. The timing of the late follicular and midluteal phase experiments was determined by pelvic ultrasound monitoring.

During the 2 years of these experiments, human corticotrophin-releasing hormone became available. Since both ovine corticotrophin-releasing hormone and human corticotrophin-releasing hormone have similar biologic action,[7] our laboratory switched exclusively to human corticotrophin-releasing hormone. Thus this latter neuropeptide was used in our experiments in women undergoing ovariectomy. Each woman undergoing ovariectomy received a subcutaneous 25 mg estradiol (E_2) pellet for estrogen replacement. This dose of E_2 maintains constant E_2 levels in the physiologic range (80 to 120 pg/ml).[8] Two to 3 months after E_2 replacement, provocative testing with human corticotrophin-releasing hormone (1 μg/kg, intravenous bolus) was performed. Medroxyprogesterone acetate, 10 mg by mouth, was then administered for 10 days. On the tenth day of medroxyprogesterone acetate administration, provocative testing with human corticotrophin-releasing hormone was repeated. During these experiments no discernible side effects were noted. This project was approved by the Human Subjects Committee of the University of California, San Diego.

Synthetic ovine corticotrophin-releasing hormone and human corticotrophin-releasing hormone were prepared in an identical fashion. Each peptide was dissolved in 5% mannitol (w/v) with 10^{-4}mol/L of ascorbic acid and sterile water at a final concentration of 200 μg/ml. The solution was then sterilized by millipore filtration, lyophilized, and stored in siliconized vials at −70° C. Corticotropin-releasing factor was reconstituted with sterile water immediately before each experiment.[9] Blood samples for ACTH were collected in 2 ml polypropylene tubes containing ethylenediaminetetraacetic acid (Sarstedt, West Germany) and promptly centrifuged at 4° C. Plasma was snap frozen in dry ice/ethanol within 10 minutes after collection and stored at −70° C until assayed. Concomitant serum samples were obtained for luteinizing hormone (LH), follicle-stimulating hormone (FSH), E_2, progesterone 4, and cortisol measurements.

ACTH was determined in unextracted plasma by radioimmunoassay in duplicate.[10] This assay uses high-performance liquid chromatography purified iodine 125–$ACTH_{1-39}$ tracer (Radioassay Systems Laboratory, Inc., Carson, Calif.) and a commercially available antiserum from the IgG Corp. (Nashville, Tennessee). Serum cortisol, LH, FSH, E_2, and progesterone concentrations were measured by previously established radioimmunoassays.[9, 11] All samples from each subject were measured in a single assay. The intraassay coefficient of variation for ACTH was 2.4% to 5.8% at standard doses between 3.3 and 34.6 pg/ml. The range of intraassay coefficient of variation for cortisol was 2.8% to 6.2% between standard doses of 40.3 and 394 ng/ml. Interassay coefficients of variation were 11.8% and 6.5% for ACTH and cortisol, respectively.

ACTH and cortisol responses were analyzed by a three-factor analysis of variance with Newman-Keuls testing to examine for potential differences in responses to corticotrophin-releasing hormone for each phase of the menstrual cycle. The integrated response curves were calculated by the trapezoid method and analyzed by the Student t test. All data are expressed as mean ± SE.

Results

Mean basal levels of LH, FSH, E_2, and progesterone during each experiment are summarized in Table I. The LH, FSH, E_2, and progesterone concentrations during each phase of the menstrual cycle are consistent with previously reported values.[12] In women undergoing ovariectomies, LH and FSH levels were elevated in comparison with normal women, although E_2 concentrations were maintained in the physiologic

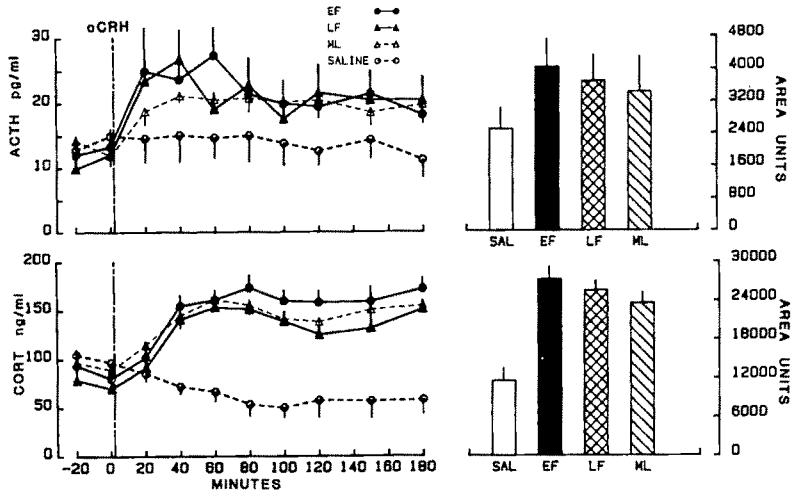

Fig. 1. *Left,* Mean (± SEM) ACTH and cortisol concentrations after the administration of saline solution or ovine corticotrophin-releasing hormone (1 μg/kg, intravenous bolus) in six women during the early follicular, late follicular, and midluteal phases of the menstrual cycle. *Right,* Integrated ACTH and cortisol responses (± SEM) to ovine corticotrophin-releasing hormone (1 μg/kg, intravenously) during the menstrual cycle.

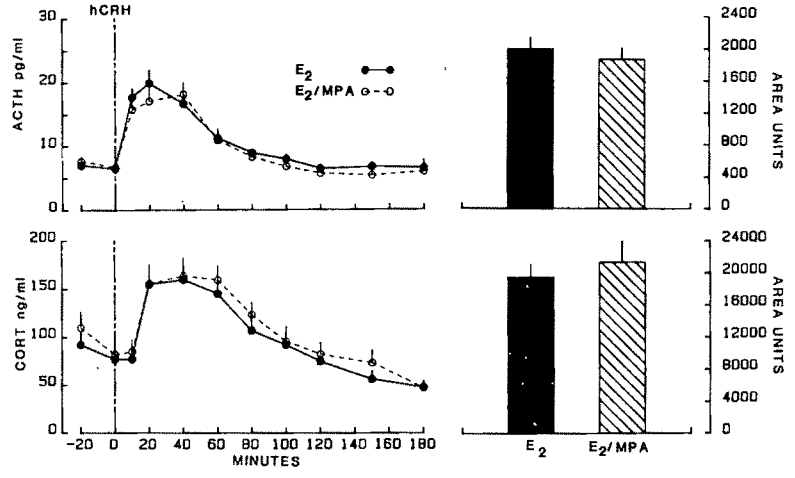

Fig. 2. *Left,* Mean (± SEM) ACTH and cortisol concentrations after human corticotrophin-releasing hormone administration (1 μg/kg, intravenous bolus) in four women undergoing ovariectomy receiving subcutaneous E_2 pellets or E_2 pellets and medroxyprogesterone acetate. *Right,* Integrated ACTH and cortisol responses (± SEM) to human corticotrophin-releasing hormone (1 μg/kg, intravenously) during E_2 and E_2 with medroxyprogesterone acetate.

range. Despite the variations in E_2 and progestin levels during each experiment, basal ACTH and cortisol concentrations were not significantly different within each group. Although basal ACTH levels were not different between the two groups, basal cortisol levels were elevated ($p < 0.01$) in women undergoing ovariectomy receiving E_2 and medroxyprogesterone acetate when compared with normal women in the late follicular phase.

During saline solution administration in normal women, ACTH levels remained stable while cortisol concentrations exhibited its characteristic midmorning decline (Fig. 1). The administration of ovine corticotrophin-releasing hormone elicited a prompt release of ACTH that reached a peak increment at 40 minutes. Peak ACTH levels were 27.3 ± 4.2, 26.3 ± 4.4, and 20.7 ± 1.0 pg/ml for the early follicular, late follicular, and midluteal phases, respectively. ACTH levels then declined but remained elevated above baseline levels during the next 2 hours. Analysis of the ACTH response curves and the integrated response for each phase of the menstrual cycle did not demonstrate

*$p < 0.01$ versus late follicular phase.

significant differences. Cortisol responses to ovine corticotrophin-releasing hormone during each phase of the cycle were parallel to ACTH, with peak increments observed at 80 minutes (Fig. 1). No significant differences in either peak or integrated cortisol responses were evident between different phases of the menstrual cycle.

In women undergoing ovariectomy receiving E_2 replacement, human corticotrophin-releasing hormone administration elicited a more rapid pituitary release of ACTH and achieved peak responses (19.9 ± 2.1 pg/ml) by 20 minutes (Fig. 2). However, the duration of ACTH release after administration of human corticotrophin-releasing hormone was much shorter than that of ovine corticotrophin-releasing hormone, with ACTH levels returning to basal levels by 100 minutes. These differences are compatible with previous reports[7] and probably reflect the longer half-life of ovine corticotrophin-releasing hormone[13] rather than intrinsic differences in the pituitary-adrenal axis between the two groups. Serum cortisol concentrations increased 10 to 20 minutes after human corticotrophin-releasing hormone and were parallel to ACTH (Fig. 2). The combination of E_2 and medroxyprogesterone acetate treatment did not affect ACTH and cortisol responses to human corticotrophin-releasing hormone.

Comment

To demonstrate the potential modulatory effects of gonadal steroids, we selected a dose of ovine corticotrophin-releasing hormone (1 μg/kg), which represented a half-maximal stimulus.[13] Similarly, the dose of human corticotrophin-releasing hormone (1 μg/kg) used in this study has been reported to be submaximal.[7] Under these experimental conditions, we have demonstrated that pituitary and adrenal responses to ovine corticotrophin-releasing hormone in women with normal cycles were not altered by physiologic fluctuations in ovarian steroid concentrations during different phases of the menstrual cycle. In addition, ACTH and cortisol responses to human corticotrophin-releasing hormone women having ovariectomy were similar during E_2 or E_2 with medroxyprogesterone acetate administration. To the best of our knowledge, this is the first study that has examined the potential modulatory role of gonadal steroids on pituitary and adrenal responses to corticotrophin-releasing hormone.

Basal ACTH and cortisol levels during each phase of the menstrual cycle were also not significantly different. These results are in agreement with Aubert et al.,[11] but are at variance with findings reported by Genazzani et al., who identified midcycle elevations in ACTH and cortisol during daily morning determinations. Since ACTH and cortisol both display accentuated episodic secretion during the morning hours,[15] this pulsatile pattern could account for the reported differences in basal hormone levels in these studies and the increased cortisol levels observed in women undergoing ovariectomy receiving E_2 and medroxyprogesterone acetate in our study.

Our present results differ from previous reports in which pharmacologic administration of estrogens and progestins appeared to exert opposite influences on the pituitary-adrenal axis. Estrogen administration has been reported to increase peripheral cortisol levels,[16] which probably reflects in part an estrogen-mediated increase in the hepatic production of corticosteroid-binding globulin.[17] In contrast, progestins appear to suppress the pituitary-adrenal axis by virtue of its weak glucocorticoid properties.[18] Both glucocorticoid and progesterone receptor complexes have been reported to share binding sites to the same regulatory region of deoxyribonucleic acid.[19] When administered in pharmacologic doses, progestins effectively inhibit corticotrophin-releasing hormone–mediated ACTH release in pituitary cell cultures,[20] inhibit ACTH synthesis and release, and can cause adrenal atrophy.[21] In our present study, however, the administration of smaller replacement doses of E_2 and medroxyprogesterone acetate in women undergoing ovariectomy had relatively little effect on basal ACTH and cortisol le-

vels or pituitary responses to corticotrophin-releasing hormone.

In summary, a comparison of the pituitary and adrenal activity under different gonadal steroid environments in women failed to demonstrate significant effects during basal or corticotrophin-releasing hormone–stimulated conditions. In view of recent reports of altered responses to corticotrophin-releasing hormone in various depressive disorders,[22] these findings would indirectly support the notion that variations in psychologic behavior and stress responses premenstrually reflect changes mediated primarily at a suprapituitary level.

We are indebted to the nurses of the Clinical Research Center for their expert assistance in these studies, and the excellent technical assistance of Carla La Porte and Gail Laughlin.

Effect of pregnancy on surgically induced endometriosis in cynomolgus monkeys

Robert S. Schenken, M.D., Robert F. Williams, Ph.D., and Gary D. Hodgen, Ph.D.
San Antonio, Texas, and Norfolk, Virginia

There are few objective data to support the clinical impression that pregnancy exerts a beneficial effect on endometriosis. In this study, we examined the progression-regression of endometriosis in pregnant and nonpregnant monkeys. Endometriosis was surgically induced in 16 monkeys and classified as minimal (n = 5), mild (n = 5), moderate (n = 4), or severe (n = 2). Monkeys were mated and pregnancy occurred in three monkeys with minimal, three with mild, and one with moderate endometriosis. Laparotomy was performed to stage the disease and to obtain biopsy specimens of implants 1 month post partum or 6 to 8 months after initial operation in nonpregnant monkeys. Monkeys with minimal and mild disease had complete regression of macroscopic disease. Histologic examination of the implants showed only fibrosis and hemosiderin deposits, except in one animal with mild endometriosis containing microscopic foci of endometrial glands. The one monkey with moderate disease had significant, but not complete regression of implants. Endometriosis in nonpregnant monkeys tended to progress. These findings demonstrate that pregnancy does exert a beneficial effect on endometriosis and suggest that pregnancy commonly results in complete resolution of minimal or mild disease. (AM J OBSTET GYNECOL 1987;157:1392-6.)

Key words: Endometriosis, pregnancy, resolution

The simultaneous occurrence of endometriosis and pregnancy is well established.[1-3] Although endometriosis may become symptomatic during pregnancy, early reports suggested that pregnancy exerts a beneficial effect on endometriosis.[4] McArthur and Ulfelder[5] critically analyzed these cases and concluded that the behavior of endometriosis during pregnancy is extremely variable. Pregnancy was followed by a reduction in size of implants in most cases, but permanent regression of endometriosis was encountered less frequently than persistent disease.

There are few objective data documenting the macroscopic and microscopic changes in endometriosis as the result of pregnancy. In conducting previously reported studies on the causes of infertility in monkeys with endometriosis, we had the opportunity to critically assess the effect of term pregnancy on surgically induced endometriosis.[6] This report describes our findings and confirms the clinical impression that pregnancy has a beneficial effect on endometriosis.

Material and methods

Twenty-one adult female cynomolgus monkeys *(Macacca fascicularis)* demonstrating menstrual cycle regularity were selected for study. Housing, feeding, and general husbandry have been described previously.[6]

Endometrial (n = 11) or adipose (n = 10) tissue was autografted to the pelvic peritoneum 3 to 5 days after the midcycle 17β-estradiol peak, as previously described.[6] Briefly, a hysterotomy was performed and resected endometrial tissue was minced and injected subperitoneally. In controls, endometrial tissue was discarded and adipose tissue injected. Laparotomy was performed during the next menstrual cycle to stage the disease and obtain biopsy specimens of the implants for histologic study.[7]

Monkeys classified as having minimal, mild, and moderate endometriosis developed peritoneal implants only. Peritoneal implants appeared as well-vascularized reddish nodules or "powder burn" deposits and ranged from 1 to 4 mm in size. Histologic examination of these areas demonstrated viable endometrial glands and stroma and hemosiderin deposits (Figs. 1 and 2). Monkeys with severe disease developed cystic adnexal masses that contained hemorrhagic, thick fluid ("chocolate cysts"). Pelvic adhesions were present only in monkeys classified as having moderate or severe disease. Biopsy of implants did not affect the macroscopic appearance or staging noted at subsequent laparotomy.

Fig. 1. Photomicrograph of biopsy specimen taken from a reddish blue peritoneal nodule. Note presence of viable endometrial glands and stroma *(arrow)*. (Hematoxylin and eosin. Original magnification ×150.)

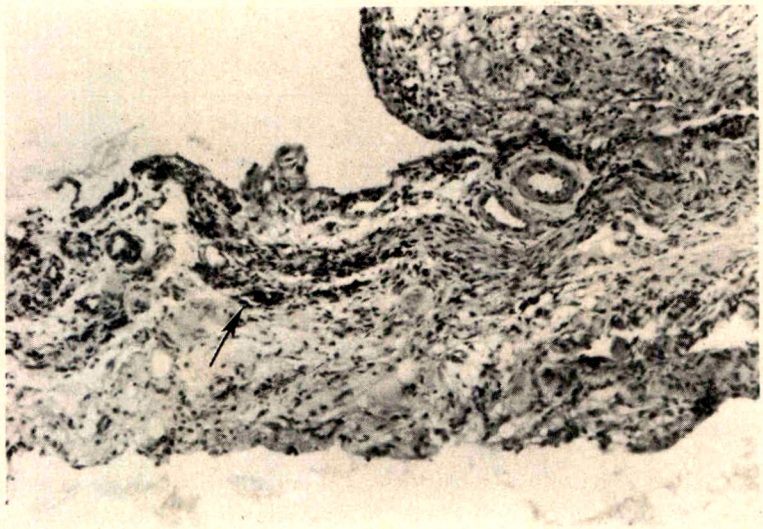

Fig. 2. Photomicrograph of biopsy specimen taken from a "powder-burn" lesion on peritoneum. Note presence of hemosiderin deposits and fragments of endometrial glands *(arrow)*. (Hematoxylin and eosin. Original magnification ×150.)

Five monkeys with adipose implants were found to have microscopic endometriosis and were classified as having minimal disease. Monkeys with endometrial autografts were classified as having mild (n = 5), moderate (n = 4), and severe (n = 2) disease (according to the American Fertility Society revised classification of endometriosis, modified to correct for the smaller size of the pelvic organs in monkeys).

During three subsequent menstrual cycles, female monkeys were mated with male animals of verified fertility. Laparotomy was performed after each mating and the extent of endometriosis and pelvic adhesions recorded. Three monkeys with minimal, three with mild, and one with moderate endometriosis delivered at term.

Laparotomy to stage endometriosis was performed 1 month post partum in pregnant monkeys and 6 to 8 months after surgical induction of endometriosis in nonpregnant monkeys. Sites of active or resolved endometriosis were sampled or resected, respectively. Specimens were serially sectioned and examined histologically. American Fertility Society classification

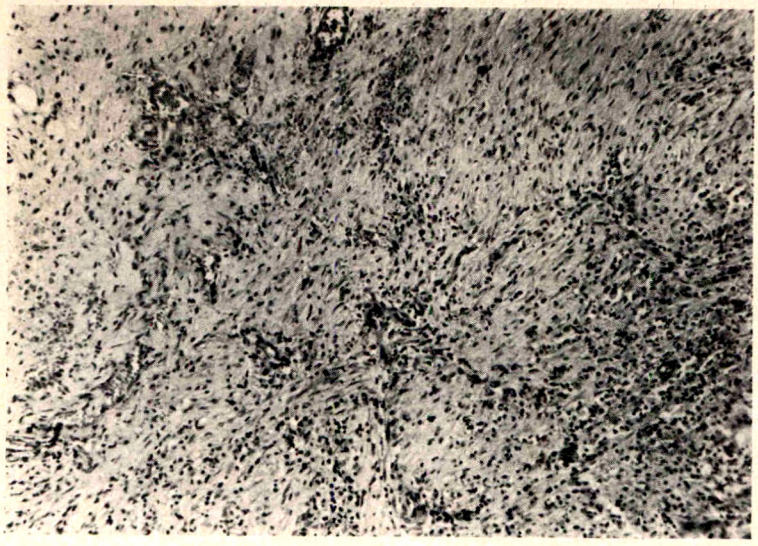

Fig. 3. Photomicrograph of biopsy specimen taken from fibrotic area of peritoneum 1 month after delivery. The biopsy site previously contained a 2 mm superficial raised reddish implant of histologically confirmed endometriosis. (Hematoxylin and eosin. Original magnification ×150.)

scores from the first laparotomy after induction of endometriosis and from the last laparotomy were compared by paired *t* tests.

Results

The American Fertility Society classification scores at the initial staging laparotomy and at the postpartum or follow-up laparotomy for pregnant and nonpregnant monkeys in each classification group are shown in Table I. Monkeys with minimal and mild disease that delivered at term had complete regression of macroscopic endometriosis. Peritoneal biopsy specimens from sites previously afflicted with endometriosis showed only fibrosis and hemosiderin deposits (Fig. 3), except in one monkey with mild endometriosis found to have foci of endometrial glands. The monkey with moderate disease demonstrated marked but not complete regression of endometriotic implants and there was no change in the severity of pelvic adhesions. A significant decrease in American Fertility Society classification score was found after pregnancy ($p < 0.05$).

In contrast, monkeys that did not become pregnant had an overall progression of disease. Endometrial implants increased in size and, in particular, pelvic adhesions increased in severity. The latter was primarily responsible for the increase in the American Fertility Society classification score in nonpregnant monkeys.

Comment

In this study, endometriotic implants demonstrated complete resolution or marked reduction in size after term pregnancy. The beneficial effect of pregnancy on endometriosis was evidenced by a significant decrease in the American Fertility Society classification score.

The lower score was due exclusively to regression of endometriotic lesions, inasmuch as no change in severity of pelvic adhesion was noted at postpartum laparotomy. Endometriotic implants did not regress in nonpregnant monkeys, indicating that regression of disease in pregnant monkeys was due to pregnancy-related factor(s) and not to spontaneous resolution.

The observed beneficial effect of pregnancy on endometriosis is consistent with previous clinical and experimental studies. In McArthur and Ulfelder's review[5] of 23 cases, endometriotic lesions tended to enlarge during the first trimester and regress as pregnancy progressed. Complete resolution of disease after pregnancy occurred infrequently. Vernon et al.[8] also reported a suppressive influence of pregnancy on the size of autotransplanted "uterine squares" (whole sections of myometrium and endometrium) in rats. Implants were not visible during pregnancy but were found on microscopic examination to contain endometrial components. Implants were again grossly detected after the peripartum surge in 17β-estradiol. The authors concluded that pregnancy temporarily suppresses endometriosis but may not cure it. In our study, complete resolution of implants did occur, but only in monkeys with minimal or mild peritoneal disease.

The mechanism(s) whereby pregnancy suppresses endometriosis is unclear. In the rat model, pseudopregnancy, in animals with or without a uterus, results in suppression of endometriotic implants.[9] These observations suggest that an extrauterine, extraembryonic pregnancy factor or factors suppress endometriosis. During pregnancy, endometriotic implants generally show stromal decidualization and flattening of glandular epithelium.[5] Prolongation of this progestational effect of pregnancy may result in stromal edema and necrosis with resultant hyalinization, fibrosis, and atrophy of implants. These changes have been observed in endometriotic implants of women and monkeys treated with high-dose progestins.[10, 11] In contrast to our findings, hormonal "pseudopregnancy" has not resulted in a cure with complete fibrosis of the endometriotic implants.[10, 11]

The variable behavior of endometriosis during pregnancy suggests that factors in addition to the gravid hormonal milieu are regulating growth and maintenance of endometriotic tissue. Recent studies have demonstrated that steroid receptor concentrations in endometriotic implants are lower than those in eutopic endometrium and up to 20% of implants do not have measurable concentrations of estrogen or progesterone receptors.[12, 14] The differences in steroid receptor concentrations are consistent with histologic and ultrastructural studies that demonstrate an incomplete morphologic response of endometriotic implants to cyclic hormonal changes.[15, 16] The favorable effect of pregnancy or progestin therapy on endometriotic implants may be restricted to implants with progesterone receptors. Surgically induced endometriotic implants may have greater progesterone receptor concentrations than do spontaneous implants and thus respond more readily to the hormonal milieu of pregnancy.

In summary, pregnancy results in significant regression of surgically induced endometriosis in cynomolgus monkeys. Fibrosis and complete resolution of implants did occur, but only in monkeys with minimal or mild peritoneal disease. These findings demonstrate that pregnancy exerts a beneficial effect on endometriosis and suggest that pregnancy commonly results in complete resolution of minimal and mild peritoneal disease.

The technical skills of Don Barber, Adrian Coleman, Dick Greenawalt, James Lewis, Almorris Lynch, Barbara Murphy, and Charlie Turner and the assistance of Eleanor Robins and Gretta Small in preparation of this manuscript are greatly appreciated.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Follicle-stimulating hormone is the main determinant of follicular recruitment and development in ovulation induction with human menopausal gonadotropin

Michael Vermesh, M.D., and Oscar A. Kletzky, M.D.
Los Angeles, California

The early hormonal changes that lead to follicular maturation and/or hyperstimulation in women requiring ovulation induction with either human menopausal gonadotropin or gonadotropin-releasing hormone have not been elucidated. This study was undertaken to assess the relative contribution of follicle-stimulating hormone and luteinizing hormone to estradiol secretion and follicular maturation in patients receiving human menopausal gonadotropin or gonadotropin-releasing hormone. The study group consisted of 10 women (26 to 38 years of age) with secondary amenorrhea as a result of hypothalamic dysfunction who had failed to ovulate when given clomiphene citrate. The patients were randomly assigned to either human menopausal gonadotropin ($n = 5$) or gonadotropin-releasing hormone ($n = 5$) treatment. On day 5 after the onset of induced menses, all women had baseline blood samples obtained at 10-minute intervals for4 hours. At this time either 150 U of human menopausal gonadotropin or 75 ng/kg of gonadotropin-releasing hormone administered hourly was given, and blood sampling every 10 minutes was continued for an additional 6 hours. Thereafter, patients were evaluated daily until ovulation. A significant and sustained increase in the mean plasma follicle-stimulating hormone level was first measured during the third hour after human menopausal gonadotropin administration ($p < 0.05$). The area under the curve of the mean plasma follicle-stimulating hormone value after this initial increase was significantly greater than its baseline (2119 ± 240 versus 1425 ± 188 mIU/ml; $p < 0.01$). This rise in mean follicle-stimulating hormone level was followed in less than 2 hours by a significant and uniform rise in mean plasma estradiol concentration ($p < 0.05$). In contrast, no immediate change in the mean levels of luteinizing hormone, follicle-stimulating hormone, or estradiol occurred after gonadotropin-releasing hormone administration. The mean daily levels of luteinizing hormone were similar in both groups; however, mean daily follicle-stimulating hormone (20.0 ± 1.1 versus 9.2 ± 1.4 mIU/ml) and estradiol (1004 ± 174 versus 495 ± 83 pg/ml) levels were significantly higher in patients treated with human menopausal gonadotropin than in those treated with gonadotropin-releasing hormone ($p < 0.001$ and $p < 0.05$, respectively). In addition, only in patients receiving human menopausal gonadotropin was a positive correlation found between mean daily plasma estradiol and follicle-stimulating hormone ($r = 0.685$, $p < 0.05$) levels and between mean daily plasma estradiol and prolactin ($r = 0.94$, $p < 0.001$) levels. In conclusion, this study suggests that follicle-stimulating hormone is the main factor involved in multiple ovarian follicular development and possible multiple gestation in patients treated with human menopausal gonadotropin. (Am J Obstet Gynecol 1987;157:1397-402.)

Key words: Human menopausal gondadotropin, follicle-stimulating hormone, ovulation induction, follicular maturation

Induction of ovulation in patients with hypothalamic amenorrhea who have failure of clomiphene citrate treatment is usually accomplished by the use of either human menopausal gonadotropin (menotropins, hMG) or gonadotropin-releasing hormone (GnRH).[1-4] Although hMG has been used extensively for many years, the mechanisms involving the initial ovarian responsivity have not been completely studied. Since both luteinizing hormone (LH) and follicle-stimulating hormone (FSH) receptors were found to be present in the follicle, it is unclear whether the LH or FSH component of hMG has greater relevance in initiating and maintaining follicular stimulation.[5] Berger and Taymor[6] reported that high doses of human pituitary FSH were ineffective in stimulating follicular estrogen secretion in patients with hypothalamic amenorrhea and concluded that LH was essential for the induction of ovulation.[6] Others have demonstrated that

the administration of human urinary FSH alone is sufficient to induce follicular growth and maturation in the presence of normal levels of endogenous LH.[7] diZerega and Hodgen[8] have suggested that in monkeys FSH is not the main determinant in establishing the final number of follicles which will ultimately ovulate.

It has been suggested that GnRH given in a pulsatile manner (every 60 to 120 minutes) induces frequent pulses of LH that reproduce the normal LH pulsatility leading to a single ovulation and pregnancy.[4, 9] However, mild ovarian hyperstimulation and multiple gestations have been reported with doses of ≥100 ng/kg/hr of GnRH, whereas 25 ng/kg/hr did not induce ovulation in all women.[4, 10]

The purpose of this study was to assess, from the inception, the hormonal dynamics leading to follicular recruitment, maturation, and ovulation in patients with hypothalamic amenorrhea treated with hMG and GnRH. The findings of these initial changes may help to elucidate the nature of multiple ovarian follicular stimulation and possible multiple gestation.

Material and methods

The study group consisted of 10 women (26 to 38 years of age) with secondary amenorrhea as a result of hypothalamic dysfunction of more than 6 months' duration, who had failed to ovulate with clomiphene citrate in doses of up to 250 mg daily for 5 days. All had a normal physical examination, were within the twentieth percentile of ideal body weight, and had no history of intensive exercise. None of these women had physical signs or laboratory test results consistent with polycystic ovarian disease. The patients were randomly assigned to either hMG (n = 5) or GnRH (n = 5) treatment. Informed consent was obtained from each individual before participation.

On day 5 after the onset of menses, induced with oral medroxyprogesterone acetate, all subjects were admitted to the Clinical Research Center and kept supine throughout the study. An indwelling catheter was inserted in an antecubital arm vein and kept open with a heparin lock. Baseline venous blood samples were obtained through the catheter at 10-minute intervals for 4 hours. At this time either 150 U of hMG (Pergonal, Serono, Randolph, Massachusetts) was given intramuscularly or 75 ng/kg of GnRH (Bachem, Carson, California) was initiated intravenously and administered hourly. Thereafter, blood sampling every 10 minutes was continued for an additional 6 hours. Patients were then discharged and followed up daily on an outpatient basis.

Those receiving hMG had the daily dose adjusted according to the levels of serum estradiol and the hMG was administered between 4:00 and 6:00 PM. The dose was increased by 50% if the serum estradiol did not double in 3 days. Each patient received a mean of 217 U or 2.9 ampules of hMG daily. Daily transvaginal ultrasound examination was performed when the serum estradiol level reached 200 pg/ml. When one or more follicles reached 17 to 19 mm in diameter a single dose of 5000 U of human chorionic gonadotropin was given intramuscularly to induce ovulation. Those patients receiving GnRH had the solution prepared with 1000 U heparin and saline solution up to a total volume of 5 ml each time refilling was required. GnRH was administered intravenously through a 4-inch-long, 19-gauge plastic catheter connected to a portable pulsatile infusion pump (Auto-Syringe, Travenol, Hooksett, New Hampshire). GnRH was delivered automatically every 60 minutes in constant doses of 75 ng/kg. This dose was expected to consistently induce ovulation without hyperstimulation.[8] With very few exceptions blood samples were obtained immediately before the hourly dose of GnRH.

All blood samples were collected between 8:00 and 9:00 AM in heparinized tubes and the plasma was separated in a refrigerated centrifuge within 1 hour and stored at −20° C until assayed. Plasma levels of LH, FSH, estradiol, and prolactin were determined by radioimmunoassay using previously described methods.[11-13] The sensitivity and the intra-assay and inter-assay coefficients of variation of the assays, respectively, were as follows: LH, 1.5 mIU/ml, 8.0% and 11.3%; FSH, 1.5 mIU/ml, 6.3% and 9.0%; estradiol, 10 pg/ml, 8.0% and 10.5%; prolactin, 2 ng/ml, 7.0% and 7.8%.

Baseline LH, FSH, estradiol, and prolactin were calculated by averaging all values obtained during the first 4 hours. Statistical analysis of frequent measurements of all hormones for the 4-hour baseline and the six initial hours after the commencement of treatment was performed by analysis of variance. In those instances in which significant changes were obtained by analysis of variance, the approximate time interval of a significant rise from the initiation of drug administration was determined by paired t test, with the Bonferroni correction for multiple comparisons with an overall significance level of $p < 0.05$.[14] To evaluate the degree of LH, FSH, estradiol, and prolactin response, the sum of the area under the concentration-time curve from the time of the corresponding significant rise to the end of 6 hours was calculated by using a computerized program.

Results of the GnRH-induced cycles were compared to those of hMG-induced cycles with the Student t test. Analysis of all daily results was standardized to the day of the midcycle LH peak (day 0). Correlation between daily hormone values was determined by linear-regression analysis. All values are given as mean ± SEM.

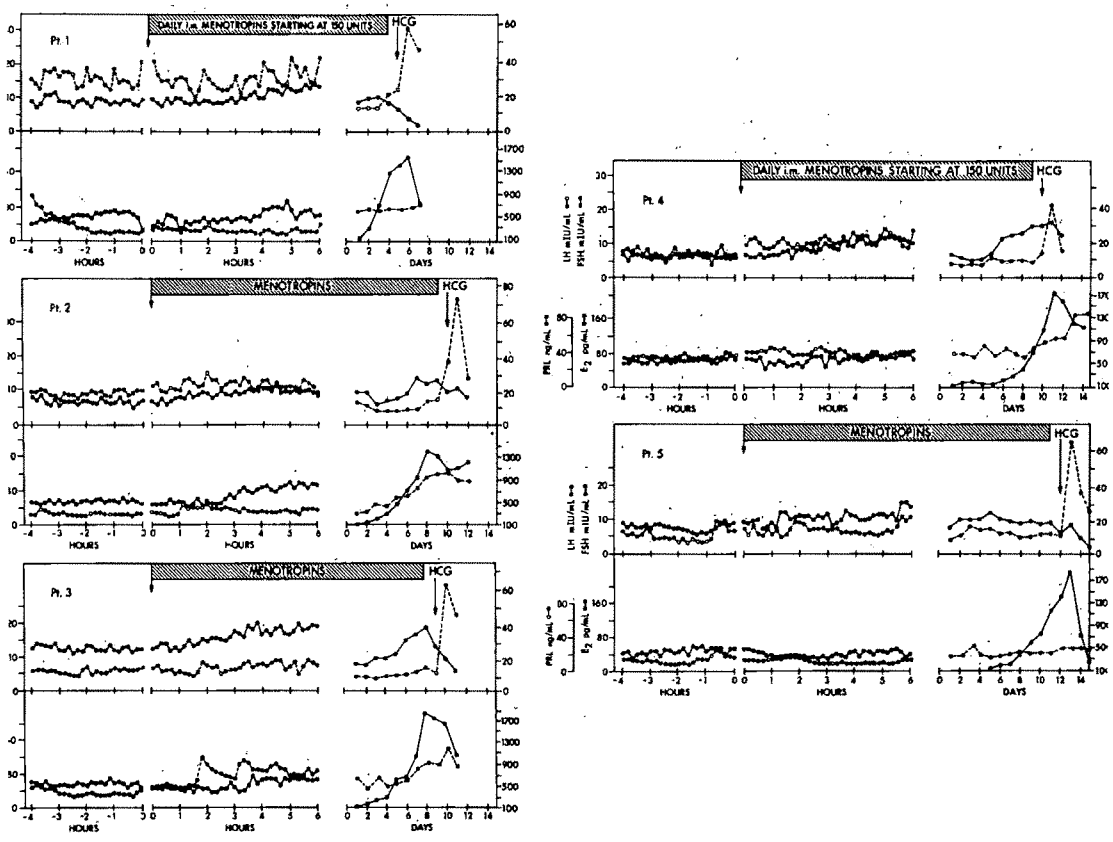

Fig. 1. Frequent (every 10 minutes) and daily concentrations of plasma LH (○) and FSH (●) *(upper panel)* and of estradiol (●) and prolactin (○) *(lower panel)* in individual patients receiving menotropins (hMG). The *scale* on the right side reflects daily levels of LH and FSH *(upper panel)* and estradiol *(lower panel)*. Time 0 hours indicates the time of initial hMG administration.

Results

Patients receiving hMG or GnRH had similar baseline levels of LH (8.3 ± 1.9 versus 6.6 ± 1.4 mIU/ml), FSH (8.3 ± 1.1 versus 6.4 ± 0.6 mIU/ml), and prolactin (19.0 ± 4.1 versus 15.0 ± 1.5 ng/ml). The plasma estradiol level was significantly lower in patients receiving hMG (54 ± 0.8 pg/ml) than in those receiving GnRH (92.6 ± 5.3 pg/ml) ($p < 0.05$). Frequent sampling before treatment revealed a variety of patterns in LH pulsatility, which would indicate that these patients represent a spectrum of abnormalities in GnRH secretion. However, both LH and FSH baselines were within the normal range for our laboratory (Figs. 1 and 2).

Approximately 150 minutes after the initiation of hMG treatment a steady and significant increase in the mean levels of plasma FSH as determined by analysis of variance was noted ($p < 0.05$). In contrast only few sporadic increases in plasma LH were found starting at approximately 3 hours after hMG administration. Furthermore, the area under the curve of plasma FSH was significantly greater than its baseline (2119 ± 240 versus 1425 ± 188 mIU/ml) ($p < 0.01$), while the increase in the area under the curve of plasma LH was of a smaller magnitude (1641 ± 283 versus 1389 ± 330 mIU/ml). Less than 2 hours after the initial and persistent FSH increase there was a significant and uniform rise in the concentration of plasma estradiol ($p < 0.05$). The area under the curve of estradiol from the rise until the end of the 6 hours (7466 ± 779 pg/ml) was significantly greater than the baseline (5613 ± 294 pg/ml) ($p < 0.05$).

The administration of pulsatile GnRH did not result in a consistent change in the levels of plasma LH, FSH, and estradiol during the initial 6 hours of treatment. However, individual patients (Numbers 3 and 4) demonstrated some increases in plasma LH, FSH, and estradiol during this time (Fig. 2). Neither stimulation regimen resulted in appreciable changes in plasma prolactin levels during the initial study period.

Mean daily levels and mean daily area under the curve of plasma LH (excluding the LH surge) in the patients receiving GnRH (18.9 ± 3.8 and 139 ± 26 mIU/ml) were not significantly different from the means found in patients receiving hMG (10.9 ± 0.9 and 91 ± 11 mIU/ml). However, mean daily levels and

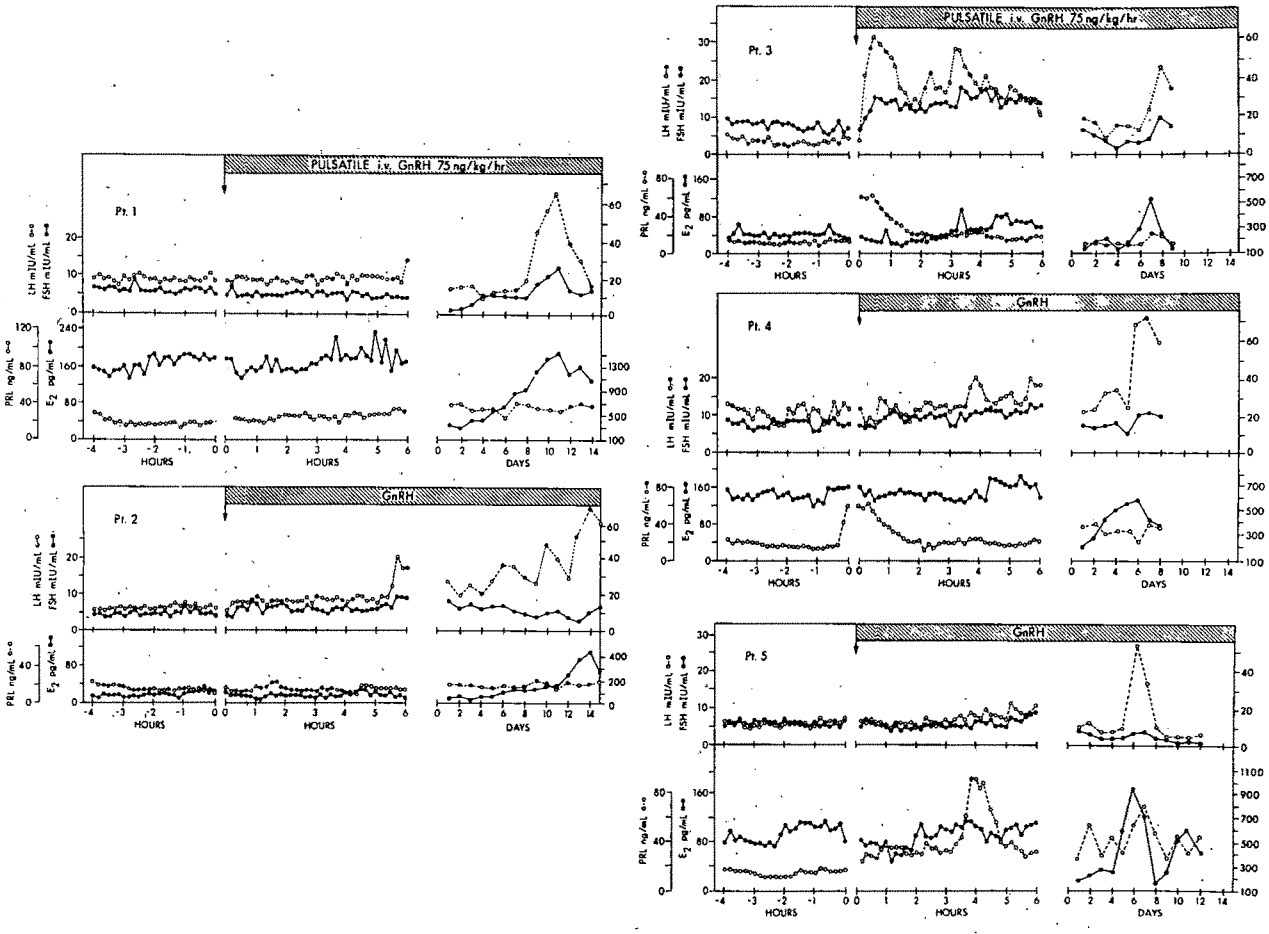

Fig. 2. Frequent (every 10 minutes) and daily concentrations of plasma LH (○) and FSH (●) *(upper panel)* and of estradiol (●) and prolactin (○) *(lower panel)* in individual patients receiving GnRH. The *scale* on the right side reflects daily levels of LH and FSH *(upper panel)* and estradiol *(lower panel)*. Time 0 hours indicates the time of initial GnRH administration.

mean daily area under the curve of plasma FSH during the same period were significantly higher in patients receiving hMG (20.0 ± 1.1 and114 ± 13 mIU/ml) than in those receiving GnRH (9.2 ± 1.4 and 53 ± 10 mIU/ml) ($p < 0.01$). Consequently, the mean LH:FSH ratio, calculated from the daily values (excluding the LH surge), was 1:2 (10.9:20.0 mIU/ml) in the hMG group and reversed to 2:1 (18.9:9.2 mIU/ml) in the GnRH-treated patients. In both groups of patients daily plasma estradiol levels increased steadily; however, during the 6 days preceding ovulation the mean plasma estradiol levels were significantly higher in the hMG group than in the GnRH-treated group (1004 ± 174 versus 495 ± 83 pg/ml) ($p < 0.05$). In addition, only in the hMG group did the mean daily plasma estradiol levels show a positive correlation with the plasma FSH levels ($r = 0.685$, $p < 0.05$) (Fig. 3).

The mean daily levels of plasma prolactin increased significantly in patients receiving hMG ($p < 0.01$). Furthermore, with the exception of Patient 1 a significant level of correlation was found between mean daily prolactin and estradiol ($r = 0.94$, $p < 0.001$) (Fig. 4). In those patients receiving GnRH a significant increase in daily plasma prolactin levels was not found, and there was no correlation between prolactin and estradiol.

The mean length of treatment required to induce ovulation did not differ between both groups (12.2 days for hMG versus 11 days for GnRH). However, those patients receiving hMG developed a mean of 4.6 mature follicles while those treated with GnRH had a mean of 1.4 follicles ($p < 0.01$). The mean largest diameter of the dominant follicle(s) for women receiving hMG was 17.7 ± 1.4 mm and for those receiving GnRH the mean was 19 ± 1.7 mm (NS).

Comment

The results of this study showed profound differences in hormonal responses to the administration of hMG and GnRH. It is conceivable that the early (<3 hours) and persistent increase in plasma FSH is the basis for hMG induction of multiple follicular stimulation that shortly thereafter resulted in a significant

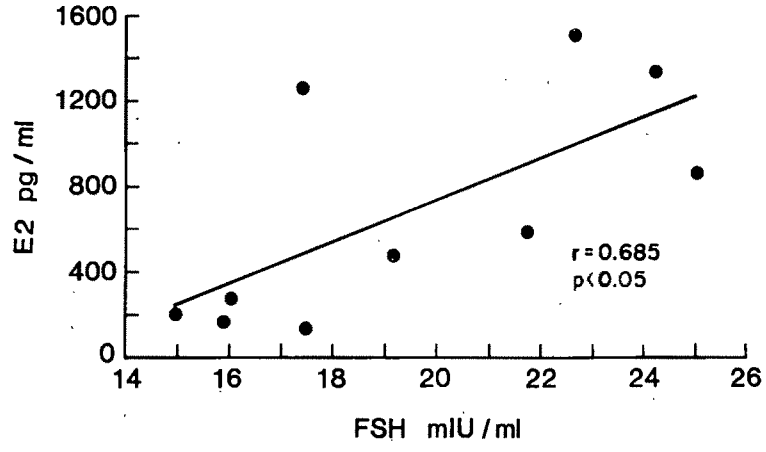

Fig. 3. Positive correlation between plasma FSH and estradiol *(E2)* in patients receiving hMG.

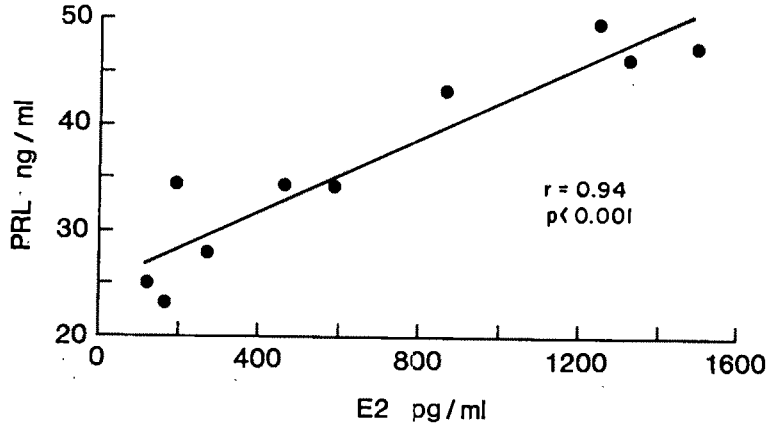

Fig. 4. Positive correlation between plasma estradiol *(E2)* and prolactin *(PRL)* in patients receiving hMG.

increase in plasma estradiol levels. This predominant FSH concentration and effect on the ovaries persisted throughout the treatment cycle as demonstrated by the reverse LH:FSH ratio that resulted in a greater number of mature follicles in the hMG-stimulated ovaries (mean of 4.6) than in the GnRH-stimulated ovaries (mean of 1.2). These results suggest that the FSH component of hMG plays a more important role than LH in initiating multiple follicular recruitment. Because of the longer half-life of FSH it is also possible that the persistent follicular stimulation by elevated FSH rescues many follicles from atresia.[15] The end result is multiple follicles that mature and ovulate if further challenged with human chorionic gonadotropin. If an excessive number of follicles is stimulated there will probably be a large amount of LH receptors. The binding of these receptors by the surrogate ovulatory dose of human chorionic gonadotropin will further stimulate those follicles, resulting in different degrees of hyperstimulation. The difference between the clearance rates of LH (30 minutes) and FSH (almost 4 hours) seems to be the cause of persistent elevated levels of FSH and only minimally elevated LH levels after the administration of a similar daily dose of each gonadotropin.[15, 16] The final blood FSH concentration and thus the degree of ovarian responsivity depends on the dose of hMG administered.

Although the LH and FSH molecular makeup of hMG is not known it seems clear that it has a significant biologic activity. It is possible that urinary gonadotropins (hMG) have a different biologic potential than those endogenously secreted after the pulsatile administration of GnRH. Although it has been reported that GnRH induces the secretion of more biologically active gonadotropins,[17] in this study a persistent ovarian response to GnRH was seen only after several days of administration. Our results do not rule out a possible role for LH in follicular development and estrogen production. Since the number of LH receptors in both human and porcine follicles has been reported to be low early in the cycle, it can be assumed that the main effect of LH is rather late in the recruitment pro-

cess.[18, 19] The progressive influence of LH is demonstrated by the absolute need for an LH signal to induce ovulation.[20] This is accomplished with human chorionic gonadotropin in hMG-treated women and with a spontaneous endogenous LH surge in GnRH-stimulated patients. Since those women with hypothalamic amenorrhea who received GnRH did not require any additional manipulation to induce ovulation, it is tempting to conclude that as long as equal pulses of GnRH are being delivered, a change in pituitary sensitivity as the result of the increasing levels of estradiol is the main pathway for the midcycle ovulatory LH surge. This is in agreement with data obtained in monkeys.[9]

It is of interest that the progressive increase in plasma estradiol levels during hMG administration was paralleled by an increase in plasma prolactin. Since these two hormones demonstrated an excellent positive correlation ($r = 0.94$, $p < 0.001$) it can be concluded that the high levels of estradiol probably directly stimulated the lactotropes. The lack of such correlation in patients receiving GnRH could be due to either the rate or the absolute degree of estradiol increase, both of which were higher in the women receiving hMG. A similar correlation has been previously reported in women treated with hMG and in pregnant women.[21, 22] However, patients receiving hMG also had higher levels of FSH and since a paracrine effect between FSH and prolactin secretion has been recently reported, such a correlation needs also to be considered.[23] However, it is doubtful that exogenously administered FSH molecules could reach and directly affect the lactotropes.

In conclusion, we have demonstrated that in women with hypothalamic amenorrhea treated with hMG but not with GnRH the concentration of FSH seems to be the main factor in the mechanism resulting in multiple ovarian follicular development and possible multiple gestation.

We wish to thank the National Pituitary Agency, Bethesda, Maryland, for their generosity in providing the reagents for radioimmunoassay of LH, FSH, and prolactin. We also wish to thank Lillian Goedert and Veret Quimby for laboratory assistance in measuring plasma LH, FSH, estradiol, and prolactin.

Human fetal breathing response to intravenous glucose is directly related to gestational age

Margaret A. Harper, M.D., Paul J. Meis, M.D., James C. Rose, Ph.D., Melissa Swain, R.N., Julia Burns, B.S., and Bruce Kardon

Winston-Salem, North Carolina

This prospective longitudinal study examined human fetal breathing activity over the second half of pregnancy both in the fasting state and after intravenous glucose administration. There was a linear relationship between gestational age and percent time spent breathing after glucose between 19 and 38 weeks' gestation. However, no such correlation could be demonstrated between gestational age and fetal breathing activity in the fasting state. (AM J OBSTET GYNECOL 1987;157:1403-5.)

Key words: Fetal breathing, gestational age, glucose

Human fetal breathing movements have been recognized since 1888.[1] The development of real-time ultrasound has greatly enhanced the study of fetal activity patterns. In particular, fetal breathing movement has been used as an example of the physiology of intrauterine development, because of its possible role in preparing the fetus for extrauterine life and as a method of demonstrating fetal well-being.[2-5]

Because spontaneous fetal breathing activity is episodic in nature, with circadian and possible ultradian biological rhythms, interest has developed in stimulating fetal breathing activity by various methods, including oral and intravenous glucose administration to the mother or increasing her inspired CO_2. Previous work suggests that glucose-stimulated fetal breathing activity varies with gestational age, with a marked increase occurring some time between 24 and 36 weeks.[6] We performed the following study to delineate more sharply the development of this fetal response in clinically healthy human fetuses.

Material and methods

Clinically healthy pregnant women between 19 and 39 weeks' gestation were selected at random from a private obstetric practice and asked to participate in the study. Over a 2-year period, all pregnant nonsmokers without medical complications and with normal prepregnancy weights were included in the random selection. Subjects with an abnormal 1-hour 50 gm Glucola screen (blood glucose >135 mg/dl) were excluded. Nineteen volunteers agreed to sequential ultrasound studies during their pregnancies. The women were certain of their last normal menstrual period, and gestational age was confirmed by physical examination in the first trimester of pregnancy and/or at least one biparietal diameter ultrasound measurement. All pregnancies had progressed normally and subsequently had normal outcomes. All 1- and 5-minute Apgar scores were 8 or more. Mean birth weight was 3422 gm.

Volunteers fasted for 8 hours before the test. Subjects underwent from two to seven fetal breathing studies. Studies in the same patient were separated by at least 1 week. All studies were carried out in a dark, quiet room with the patient resting in bed in the left lateral recumbent position. Observations of the fetuses were made with a real-time ultrasound linear array scanner (Advanced Diagnostic Research, Tempe, Arizona). The hand-held transducer operated at a frequency of 3.5 mHz. Images from the scanner display screen were recorded on a videotape recorder (Sony Corporation, Japan) for analysis. After observation of the fetuses for a 20-minute control period, a bolus dose of 25 gm of 50% dextrose was administered over 20 seconds through an antecubital vein. Ultrasound observations of the fetuses were continued for an additional 60 minutes. On subsequent replay, individual fetal breathing movements were identified on the video monitor and coded on a chart recorder with an event marker as described by Patrick et al.[7] Fetal breathing activity was defined as inward movement of the chest wall echoes with outward movement of the abdominal wall echoes. Continuous breathing was considered present when the interval between breaths was less than 6 seconds. During the 80-minute observation period, fetal breathing activity as percent time spent breathing was analyzed for the four successive 20-minute periods (P_1, −20 to

0 minutes; P_2, 0 to 20 minutes; P_3, 20 to 40 minutes; and P_4, 40 to 60 minutes). A relatively short observation period (20 minutes) may facilitate the ease of clinical application of stimulated fetal breathing studies; 20 minutes was therefore also used as the control period. Seventy-two studies were completed and all data were used in statistical analysis.

Statistical methods. A scatterplot was obtained of the raw data for each time period. Spearman rank correlation coefficients were determined for P_1 thru P_4. Regression analysis was carried out for P_4 because it had the highest correlation coefficient. Because of unequal sample sizes and unequal variance for the different gestational ages studied, regression was performed on the weighted means. Several transformations were attempted to find the formula of best fit for P_4. Multivariant analyses of variance in the SPSS and SAS programs were used to determine significance between the different time periods. A significance level of 0.05 was chosen.

Results

Spearman rank correlation coefficients showed a significant correlation between percent time spent breathing and gestational age for all three periods ($p < 0.01$) after intravenous glucose, but not in the fasting state ($p > 0.10$; Table I). The 40 to 60–minute time period had the highest correlation coefficient (0.531), so it was chosen for regression analysis to model the relationship (Fig. 1). Linear regression on the raw data yielded an r^2 value of 32.6% and an F statistic for the slope of 33.79 (1,71; $p < 0.005$). A normal probability plot of residuals was approximately a straight line. Regression analysis on the weighted means yielded the highest r^2 value (0.882) for the form: $y = -17.15 + 0.042x$ (gestational age)^2 (see Appendix).

Multivariant analysis of variance showed that 20 to 40 and 40 to 60 minutes after intravenous glucose, the percent time spent breathing by the fetus is significantly different from the percent time spent breathing in the 20-minute control period ($p = 0.001$).

Comment

This study confirms that glucose-stimulated (but not unstimulated breathing) fetal breathing activity has a significant positive correlation with gestational age in the last half of pregnancy in healthy, human fetuses. This is the first study that has attempted to model this relationship and develop regression forms that might predict fetal breathing response at various gestational ages.

Fetal breathing activity has interested investigators and clinicians for a number of reasons. The increased occurrence of this activity over the latter part of gestation is a measurable marker of maturation of a vital neonatal function. The development of this function parallels other maturational events in the fetal lung.[8] The occurrence of spontaneous breathing activity correlates with fetal well-being, and fetal asphyxia or hypoxemia is accompanied by prolonged apnea.[5] Patients in active labor are reported to have diminished fetal breathing activity, while parturients who have uterine contractions in the absence of cervical changes (false labor) have undiminished fetal breathing. Thus the presence or absence of fetal breathing has been suggested as a sign of "true labor."[9]

Because the occurrence of fetal breathing is episodic and healthy fetuses may have periods of apnea lasting 60 minutes or more, stimulation of fetal breathing, by one of several techniques, is attractive as an alternative to long spans of observation for spontaneous breathing activity. The observation of stimulated fetal breathing or its absence has been found useful in the identification of abnormal fetuses[10-13] and the prediction of the likelihood of delivery for women in true or false labor.[9]

In the evaluation of amounts of fetal breathing stimulated at various times of gestation, normative data obtained from healthy pregnancies must be developed. Our study represents an important step in the development of a longitudinal body of data for fetal breathing stimulated by an intravenous glucose infusion. Similar longitudinal studies of pregnancies complicated by hypertension or fetal growth retardation may be valuable in assessing deviations from patterns observed in health.

Sonographic amniotic fluid measurement and fetal growth retardation: A reappraisal

Robert M. Patterson, M.D., Thomas J. Prihoda, Ph.D., and Margaret R. Pouliot, R.N.
San Antonio, Texas

Sonographic estimation of amniotic fluid volume is commonly used as a diagnostic test for oligohydramnios associated with fetal malnutrition. However, methods of measurement and diagnostic criteria are controversial. We prospectively evaluated the reproducibility of amniotic fluid diameter measurement and studied various threshold definitions of oligohydramnios as predictors of small for gestational age fetuses or fetuses with low ponderal index values. An average of the vertical and two perpendicular horizontal diameters of the largest pocket of amniotic fluid was more reproducible than the maximum vertical pocket and better enabled a single observer to differentiate between patients. An average diameter of 10 mm was highly diagnostic of small for gestational age fetuses but was insufficiently sensitive (27%) to serve as a screening test. Although also of limited sensitivity (40%), an average diameter of approximately 30 mm was probably the best screening threshold. Reduced average diameter was significantly related to the occurrence of a ponderal index less than or equal to the tenth percentile for dates. Three of seven (43%) neonates with a ponderal index less than or equal to the tenth percentile and a birth weight greater than the tenth percentile for dates had a low average diameter, suggesting that reduced average amniotic fluid diameter may help to identify the malnourished fetus with birth weight greater than the tenth percentile for dates. (Am J Obstet Gynecol 1987;157:1406-10.)

Key words: Amniotic fluid, fetal growth retardation, ultrasound

Amniotic fluid volume is reduced among fetuses suffering chronic uteroplacental insufficiency with intrauterine malnutrition. In the past decade, ultrasonography has been used extensively in an attempt to estimate amniotic fluid volume and predict poor fetal growth.[1-7] However, the usefulness of this technique is controversial.[7-9] Among the various reports, the technique of amniotic fluid estimation varies from subjective to objective. Among the reports of objective assessment, technique varies from measurement of the broadest dimension of the largest pocket of fluid[2-4] to measurement of the maximal vertical depth of the largest pocket.[6,7] Criteria for "oligohydramnios" vary from <1 cm to <3 cm.[2-4,6,10] Even when objective criteria are used, some studies find amniotic fluid estimation to be a highly diagnostic test,[2] whereas others, reporting on unselected populations with a low prevalence of fetal malnutrition, have found the test insensitive and of little use as a screening tool.[3,5,7] In addition to questions of test reliability and usefulness, most of the published data on amniotic fluid measurement fail to consider the heterogeneity of aberrant fetal growth. Most reports have evaluated decreased amniotic fluid volume and the occurrence of birth weight below the tenth percentile for gestational age. Except in the postdate pregnancy,[11] the relationship of decreased amniotic fluid diameter to the occurrence of low ponderal index is largely unexplored.

These controversies prompted us to reevaluate the real-time ultrasonographic estimation of amniotic fluid volume and to reexamine its usefulness as a test for fetal malnutrition. The purposes of this study were: (1) to evaluate the reproducibility of two objective methods of measurement of amniotic fluid diameter; (2) to evaluate the relationship of the most reproducible method to the occurrence of birth weight below the tenth percentile for gestational age, as well as low ponderal index (less than or equal to the tenth percentile for dates); and to evaluate the effectiveness of various diagnostic thresholds of amniotic fluid diameter measurement as predictive tests for poor fetal growth in a population at risk.

Methods

In order to evaluate the reproducibility of amniotic fluid measurement, the frequently reported maximal vertical pocket was compared to an average of three diameters of the largest pocket of amniotic fluid. Consecutive patients were examined ultrasonographically by two independent observers after 20 weeks' gestational age. All examinations were performed with a

Variability within patients	70.90	23.69	144.85	75.66	103.81	49.68

MVP = Maximum vertical pocket; AD = average amniotic fluid diameter.

General Electric RT 3000 real-time ultrasound machine equipped with a 3.5 or 5.0 MHz linear array transducer. At the beginning and at the end of each examination, all four uterine quadrants were inspected. The vertical and the two perpendicular horizontal diameters of the largest pocket of amniotic fluid that was free of umbilical cord and extremities were measured and averaged. Therefore each independent observer measured the largest pocket of fluid at the beginning and end of each examination. Neither observer was aware of which pocket was measured or of the values recorded by the other observer.

The data were evaluated by analysis of variance and by maximum likelihood estimates of the variance components between and within subjects.

Subsequently, the three diameters of the largest pocket of amniotic fluid were measured prospectively in consecutive clinic patients at risk for fetal malnutrition. Indications for examination included prepregnant weight <100 pounds, weight gain <5 pounds by 20 weeks' or <10 pounds by 30 weeks' gestational age, essential hypertension, collagen vascular disease, chronic renal disease, previous infant with birth weight less than or equal to the tenth percentile for gestational age, narcotic or tobacco addiction, or fundal height measurement lagging ≥5 weeks behind gestational age. Amniotic fluid diameter measurement did not influence patient management. In each patient, the examination done between 20 and 40 weeks' gestational age and nearest to delivery was selected for analysis.

Gestational age assignment was by best obstetric estimate based on a combination of last menstrual period, early examination, ultrasonography, and confirming neonatal Dubowitz examination. Crown-heel length measurements and Dubowitz examinations were performed at approximately 24 hours of life by trained personnel. Crown-heel length was obtained by means of the tonic-neck reflex on a measured bed. Small for gestational age or low ponderal index was defined as a birth weight or ponderal index less than or equal to the tenth percentile for gestational age.[12, 13]

After delivery, the data were evaluated by linear regression, χ^2, and Fisher's exact analyses where appropriate. Receiver-operating characteristic curve anal-

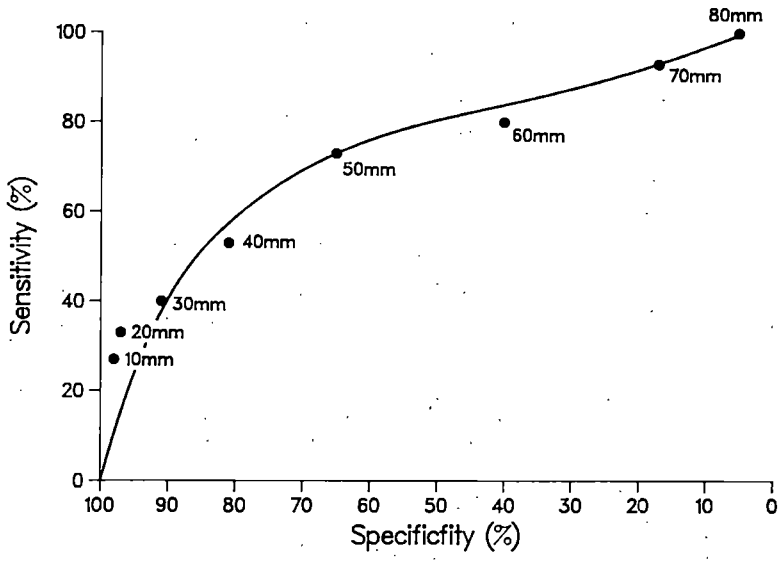

Fig. 2. Receiver-operating characteristic curve of average amniotic fluid diameter as a test for the small for gestational age fetus.

ysis was used to evaluate amniotic fluid diameter measurement as a diagnostic test for small for gestational age and low ponderal index.

Results

Initially 20 patients were examined. The means for vertical diameter and for average diameter were 40.85 and 50.89 mm, respectively. For vertical diameter, the variability between subjects was 100.57 mm^2 and the variability of the average diameter from subject to subject was 222.76 mm^2.

Within a subject, the intraobserver variability of the vertical diameter was 103.81 mm^2 with a coefficient of variation of 25.43%. In comparison, the intraobserver variability of the average diameter was 49.68 mm^2 with a coefficient of variation of 13.85% ($p = 0.2$) (Table I). There was no significant interobserver variability with either method.

Fig. 1 demonstrates that the intraobserver variability of the vertical diameter exceeded the difference between patients. Therefore a single patient with measurements done at two different times by the same observer might appear very different. In contrast, the interpatient variability of average diameter was more than four times greater than the intraobserver variability. This would enable a single observer to differentiate better between patients.

Seventy-eight patients at risk for fetal malnutrition were subsequently examined. Mean gestational age at the time of examination and at delivery was 33 ± 4 and 38 ± 3 weeks, respectively. The mean average diameter was 51 ± 21 mm. The measurement was 51.7 ± 19.2 mm among 15 patients examined before 36 weeks and 52.4 ± 21.2 mm among the 63 examined after 36 weeks. Linear correlation analysis showed average diameter to be independent of gestational age ($r = 0.1058$, $p = 0.3556$). However, it was significantly related to birth weight ($r = 0.4469$, $p = 0.0001$). Fifteen of 78 (19%) infants were small for gestational age. Crown-heel length was not measured in two neonates with early death. Eighteen of the remaining 76 (23.7%) had low ponderal index values.

The receiver-operating characteristic curve analysis evaluating average diameter as a diagnostic test for small for gestational age is presented in Fig. 2 and Table II. Although average diameter was significantly related to the occurrence of small for gestational age, it was insensitive. A threshold of 10 mm was only 27% sensitive; however, it was highly diagnostic and it represented the most efficient application of the test. At a threshold of approximately 32 mm, the sensitivity, specificity, and positive and negative predictive values were 40%, 91%, 50%, and 86%, respectively. At this cutoff point, 15% of the study population was classified as abnormal.

The relationship between an average diameter ≤32 mm and the occurrence of small for gestational age or low ponderal index value was then evaluated. The accuracy of the average diameter at predicting small for gestational age was not related to the interval between examination and delivery ($p = 0.2169$). However, the relationship between average diameter and the occurrence of low ponderal index value was significant only in 53 patients examined <3 weeks before delivery ($p = 0.0009$).

An average diameter ≤32 mm was significantly

Table II. Thresholds of average amniotic fluid diameter as diagnostic tests for the small for gestational age fetus

Average diameter (mm)	*Sensitivity (%)*	*Specificity (%)*	*Positive predictive value (%)*	*Negative predictive value (%)*	*% with abnormal test (N = 78)*	*p Value*
≤40	53	81	40	88	26	0.01
≤30	40	91	50	86	15	0.009
≤20	33	97	71	86	9	0.002
≤10	27	98	80	85	6	0.004

related to the occurrence of both small for gestational age (p = 0.0341) and low ponderal index value (p = 0.0089). Average diameter was low among three of seven (43%) patients with low ponderal index values and birth weights greater than the tenth percentile and among four of six (67%) with low ponderal index values and small for gestational age (Table III).

Table III. Average amniotic fluid diameter as diagnostic test for birth weight or ponderal index less than or equal to the tenth percentile for gestational age in patients examined within 3 weeks of delivery

	Birth weight		*Ponderal index*

≤32 mm	7	8	7	6
>32 mm	7	33	6	34
Total No. of patients	55		53	
p Value*	0.0341		0.0089	

*An average diameter ≤32 mm was significantly related to small for gestational age and low ponderal index.

Comment

Controversy exists regarding the method of amniotic fluid measurement, the definition of "abnormal amniotic fluid volume" and the type of "growth retardation" most likely to be associated with low amniotic fluid volume.[2-10] Receiver-operating characteristic curve analysis was used to evaluate diagnostic thresholds for the maximal vertical pocket in a recent report by Bottoms et al.[7] In that report, the vertical diameter was not found to be useful as a screening test for small for gestational age in a low-risk population. Interestingly, the authors postulated that the varied pathophysiologic features of atypical intrauterine growth might partially explain the variable test performance reported in the literature. For example, normal small fetuses do not have uteroplacental insufficiency, and they usually have normal amniotic fluid volume. In contrast, fetuses with malnutrition may have oligohydramnios regardless of birth weight. This controversy prompted us to evaluate the reproducibility of amniotic fluid volume estimation, the usefulness of the test in a population at risk, and the relationship between amniotic fluid status and the occurrence of poor fetal nutrition, defined as a ponderal index less than or equal to the tenth percentile or birth weight less than or equal to the tenth percentile for dates. We chose to evaluate only objective criteria for volume estimation, feeling that an objective measurement would be more widely reproducible.

Although these data do not establish the average diameter as the best of all possible measurements, they clearly demonstrate the superiority of measuring multiple diameters over measuring only one diameter. Measuring three dimensions of amniotic fluid may make the measurement more robust to changes in fetal and maternal position. Furthermore, the finding that the intraobserver variability of the vertical diameter exceeds the variability between patients provides an explanation for the poor performance of the vertical measurement reported in previous studies.

As expected, the receiver-operating characteristic curve analyses for average diameter demonstrated that the appropriate diagnostic threshold depends on the desired use for the test. The 10 mm level, which is similar to the "1 cm rule," was found to be diagnostic and efficient but was insufficiently sensitive to function as a screening test. At approximately the 30 mm level, the sensitivity, specificity, and predictive values were similar to those reported for the nonstress test, perhaps our most commonly used screening test.[14]

Because of sample truncation, we cannot fully evaluate the average diameter across all gestational ages. However, it appears to be stable at 51 ± 21 mm between approximately 28 and 40 weeks' gestational age, the time at which most examinations for growth retardation are done. This gestational age independence makes the average diameter an attractive test among patients with questionable dates.

Evaluation of the relationship between average diameter and the occurrence of ponderal index values less than or equal to the tenth percentile for dates addresses the issue of differentiating "fetal malnutrition" from "small for gestational age." Interval between the

examination and delivery significantly affected the ability of average diameter to predict low ponderal index values but had no effect on the prediction of small for gestational age. This finding is in keeping with our understanding of the continuum of intrauterine growth retardation. In a pregnancy undergoing placental senescence, a presumably well-nourished fetus first suffers depletion of fat stores. The fetus may become thin (low ponderal index value) relatively quickly and may develop low amniotic fluid volume. However, gross fetal weight declines more slowly, presumably by failure of growth. This sequence is the presumed pathogenesis of postmaturity syndrome.[10, 11] Therefore more frequent examination may be necessary to identify declining fetal fat stores. In this study, there were seven neonates with low ponderal index values and birth weight above the tenth percentile for gestational age. Forty-three percent of those had low average diameter. Thus the test identified some malnourished fetuses with apparently normal weights. These data corroborate the suggestion of Bottoms et al.[7] that the previously reported limitations of amniotic fluid measurement may be due to the varied pathophysiologic characteristics of "small for gestational age" in the populations studied. It is unreasonable to expect a normal, though small fetus to have oligohydramnios.

In summary, these data demonstrate that the average diameter of the largest pocket of amniotic fluid is more reproducible than the maximal vertical diameter and better enables a single observer to differentiate between patients. The frequently recommended threshold of amniotic fluid diameter of 1 cm was highly diagnostic and was the most efficient of the thresholds tested. However, it was insufficiently sensitive to serve as a screening test in women at high risk for fetal malnutrition. An average amniotic fluid diameter of approximately 30 mm probably represents an appropriate screening threshold for such populations. Reduced amniotic fluid diameter may help to identify the malnourished fetus who may not be small for gestational age.

Ultrasonic prediction of birth weight in preterm fetuses: Which formula is best?

Bruce W. Pielet, M.D., Rudy E. Sabbagha, M.D., Scott N. MacGregor, D.O., Ralph K. Tamura, M.D., and Seth L. Feigenbaum, M.D.

Chicago, Illinois

Data from previous studies have suggested that birth weight prediction was enhanced by using formulas specifically derived from preterm fetuses. However, no prospective comparison of different formulas was performed. We obtained ultrasonic data on 61 pregnancies at risk for preterm delivery with a gestational age of 29.0 ± 3.0 weeks (mean ± SD). In all women birth weight was predicted within 7 days of delivery. Of the 61 pregnancies, 49 (80%), 41 (67%), 30 (49%), and 17 (28%) weighed <1750, 1500, 1250, and 1000 gm, respectively; 14 published formulas were compared for accuracy in predicting birth weight in these four categories. The formulas with the smallest absolute mean percent errors incorporated head and abdominal circumferences and femur length. The formula of Weiner et al., derived from low birth weight infants, produced the smallest absolute mean percent error and SD, 10.9% ± 7.9%; this error was further reduced to 7.7% ± 6.5% in infants weighing <750 gm. These findings suggest that birth weight in the preterm fetus is best predicted by a formula targeted to such a population. (Am J Obstet Gynecol 1987;157:1411-4.)

Key words: Accuracy, low birth weight, targeted formula

Accurate sonographic estimates of fetal weight are instrumental in the management of women at risk for preterm delivery. Formulas used in predicting fetal weight have been mainly derived from measurements obtained in the term or near-term pregnancy and then extrapolated to the preterm fetus.[1-7] However, the

accuracy in estimation of fetal weight has been shown to improve by the use of formulas specifically derived from a population at high risk for preterm delivery.[8-12] This enhanced accuracy may be related to the fact that "targeted" formulas account for the large head-to-abdomen ratio, a characteristic of the preterm fetus.

In the management of women at risk for preterm delivery it is important to know which formula is the most accurate predictor of weight in fetuses <2000 gm. Such information impacts on management decisions pertaining to route of delivery. Additionally, in very small fetuses size is one of the crucial factors in determining potential viability.

In this prospective study, 14 published weight-predicting formulas are compared for relative accuracy in the low and very low birth weight categories.

Material and methods

Ultrasonic fetal measurements were prospectively obtained within 1 week of delivery in 75 pregnant women who were seen consecutively and who were at high risk for preterm labor. In all patients, we used one of two ultrasound machines: an Ultramark 4 or a G.E. 3000. Echograms were obtained by one of the authors in accordance with previously described methodology, using linear array transducers with a frequency of 3.5 MHz.[13-15] The trackball located on the operating board of the ultrasonic equipment was manipulated to measure biparietal diameter, head circumference, abdominal circumference, and femur length.

Fourteen of 75 fetuses were excluded from the study because one or more of the sonographic parameters were technically unobtainable or actual birth weight was >2000 gm. Data from the remaining 61 fetuses were used to test the accuracy of 14 previously published formulas (Table I). The three most accurate formulas in the low and very low birth weight categories were identified and the birth weight estimates were compared to actual size. Additionally, comparisons were made with Shepard's formula because it was one of the first formulas used (Tables I, II, and III).

Mean percent and absolute mean percent differences between predicted and actual birth weights were calculated. The accuracy in prediction was compared in relation to 250 gm increments in size (Table II). Additionally, the percentages of infants with predicted weights falling within 5%, 10%, and 15% of actual weights were computed in the very low birth weight category (<1000 gm) (Table III).

Statistical analyses were performed with the Statistical Package for Social Sciences. Testing for significant differences in the 14 formulas was performed by analysis of variance.

Results

The mean (±SD) gestational age in the 61 fetuses studied was 29.0 ± 3 weeks. The birth weights ranged from 470 to 1965 gm with a mean (±SD) value of 1293 ± 423 gm. Of the 61 infants studied, 80% (49/61), 67% (41/61), 49% (30/61), 28% (17/61), and 10% (6/61) weighed <1750, 1500, 1250, 1000, and 750 gm, respectively.

The errors in estimation of birth weight and the coefficients of determination obtained by the three most accurate formulas and that of Shepard et al. are shown in Table II. The formula published by Weiner et al. (Equation 10, Table I) was the most accurate estimator of actual size in low birth weight infants. In contrast to results for other formulas, this accuracy was further

Mean percent error = −4%/2 = −2%. Absolute mean percent error = 28%/2 = 14%.

improved in infants with birth weight <750 gm (Table II). Specifically, the differences in absolute mean percent errors between the formula by Weiner et al. and the other three formulas was statistically significant in weight categories <1500 gm ($p < 0.05$). The formula by Weiner et al. also had a consistently greater percentage of fetuses within a specified range of percent error (Table III); these advantages were not apparent when mean percent errors, rather than absolute mean percent errors were compared (Table II).

Comment

Different ultrasonic parameters have been used to generate a number of mathematical formulas to estimate fetal weight (Table I). However, only a few of these formulas were targeted to specific groups such as women at high risk for preterm labor or intrauterine growth retardation.[8-11] In this prospective study, we show that the formula derived by Weiner et al., which is targeted to women at high risk for preterm labor, is the most accurate method in predicting size in low birth weight fetuses (Tables I, II, and III). It should be noted that this formula was previously derived from a similar population of fetuses in the midwestern area of the country.

In previously published formulas accuracy was mainly determined by comparing the mean percent errors between predicted and actual birth weights. However, in such comparisons, negative and positive differences may cancel each other. By contrast, when the absolute mean percent error is used, the average of the sum of actual differences regardless of the directional sign is computed. In this way a true estimate of the error is obtained. The difference between mean and absolute mean percent errors in two fetuses with the same birth weight of 1000 gm is shown in Table IV; the difference is marked: −2% versus 14%.

It is apparent that the mean percent error is misleading because it reduces the difference between predicted and actual birth weights. Thus, when mean percent error is used, caution should be exercised in quantifying potential variation from actual size.

A comparison of the best three formulas in our study is shown in Table II. The absolute mean percent error, reflecting true potential difference, is consistently smaller with the formula derived by Weiner et al. Interestingly, the mean percent errors are smaller with Hadlock's formula. This is related to the fact that with Hadlock's formula the positive and negative predictions are more evenly distributed about the mean and therefore cancel each other.

Importantly, the absolute mean percent error decreases in fetuses with very low birth weight (<1000 gm) only when the formula published by Weiner et al. is used (Table II). The enhanced accuracy of the latter formula is also shown in Table III; specifically, in infants weighing <1000 gm, the predicted weight falls within 15% of the actual birth weight in 88% of cases.

Our prospective analysis also shows that birth weight is generally overestimated with the formula published by Hadlock et al. and underestimated by that of Weiner et al. (Table II). Knowledge of whether ultrasonic or even clinical estimates of birth weight tend to exceed or fall short of actual size is important.[16] For example,

in the management of a fetus near the limits of viability (25 to 26 weeks' gestation and 500 to 600 gm in weight) the decision-making process regarding possible operative intervention will partly depend on whether the method used will underestimate or overestimate birth weight.

In summary, analysis of the present series suggests that the most accurate estimates of size in low birth weight infants is obtained by using a formula targeted for that group. The formula derived by Weiner et al. is best in this respect. In evaluating the accuracy of a weight-predicting formula, emphasis should be placed on the standard deviation as well as the absolute mean percent error. Finally, knowledge of whether a particular formula is more likely to underestimate or overestimate the prediction of birth weight is helpful in particular circumstances.

Effects of the antiprogesterone RU 486 in normal women

I. Single-dose administration in the midluteal phase

Donna Shoupe, M.D., Daniel R. Mishell, Jr., M.D., Pekka Lahteenmaki, M.D., Oskari Heikinheimo, M.D., Lars Birgerson, M.D., Hosam Madkour, M.D., and Irving M. Spitz, M.D.

Los Angeles, California, New York, New York, Uppsala, Sweden, and Helsinki, Finland

The response to a single oral dose of the antiprogesterone RU 486 was studied in the midluteal phase in 26 normal women. Each subject received a dose between 50 and 800 mg RU 486 on days 6 to 8 after the luteinizing hormone surge and blood samples were taken over the following 48 hours. Another group of five patients received a single oral dose of 200 mg RU 486 and blood sampling was extended for 14 days. Menses were induced in all women but one within 3 days after RU 486 administration. Two distinct patient populations emerged. In nine of the subjects, there was a single bleeding episode and the treatment cycle was significantly shorter ($p < 0.05$) than the following cycle. In 16 of these 25 patients a second bleeding episode occurred 19.0 ± 0.8 days after the luteinizing hormone surge. The total treatment cycle was significantly prolonged ($p < 0.05$) when compared with the following cycle. In the group with a single bleeding episode, there was a significant decline in follicle-stimulating hormone, estradiol, and progesterone over the 48-hour sampling period, but there was no change in these values in the group with two bleeding episodes. These two groups could not be separated on the basis of RU 486 dose or serum levels. After the four higher doses, there was a dose-dependent rise in serum prolactin. There were no alterations in mean cortisol values with the three lower doses, but there was a significant increase at 24 and 48 hours after the higher doses. Serum levels of RU 486 were maximal between 1 and 4 hours and the half-life of serum RU 486 was determined to be 24 hours. (Am J Obstet Gynecol 1987;157:1415-20.)

Key words: RU 486, contraception, gonadotropins, steroids

The synthesis and development of RU 486, a 19-norprogestin derivative, is considered a major breakthrough in steroid endocrinology[1] and has opened a new era in fertility control. Beyond its potential use in contraceptive technology, the antiprogestational[1] and antiglucocorticoid[2-4] activities of RU 486 serve as a unique tool for investigation of hormone action.

In early reports, RU 486 has been noted to interrupt the luteal phase in women[4-6] and in monkeys[6] and to terminate early pregnancy.[7, 8] RU 486 has also been shown to have an affinity for the glucocorticoid receptor that is about four times higher than that of dexamethasone and has been shown to have antiglucocorticoid activity. After a single oral dose of RU 486, there is a transient increase in adrenocorticotropic hormone.[2, 3]

The aim of this study was to investigate the effect of a single oral dose of RU 486 on bleeding, gonadotropin, and steroid patterns given to healthy women in the midluteal phase. In addition, the pharmacodynamics of this compound were studied with a recently developed radioimmunoassay.

Material and methods

Thirty-one healthy women, whose ages ranged from 22 to 35 years, were selected for participation in this study. They had regular menstrual cycles (28 ± 3 days) and were within 15% of their ideal body weight. They either had been surgically sterilized or had used a barrier method for contraception. The volunteers had not taken any steroid medication within the last 6 months.

On the tenth day of the menstrual cycle, each patient began to undergo daily blood sampling for determination of the day of the luteinizing hormone (LH) surge. Six to eight days after the LH surge, the volunteers were asked to report at 7:30 AM, after an overnight fast, and to refrain from smoking after midnight for administration of medication.

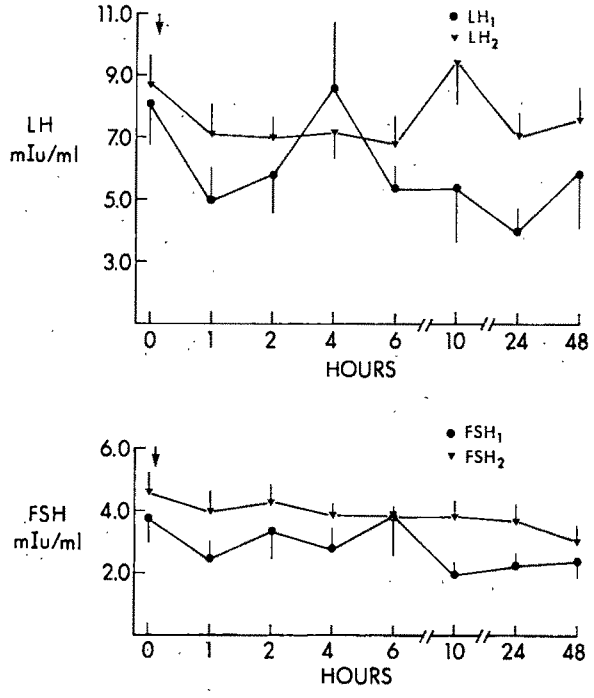

Fig. 1. LH *(upper panel)* and FSH *(lower panel)* values after a single oral dose of RU 486 ranging from 50 to 800 mg. LH_1 and FSH_1 refer to the patients with one bleeding episode after RU 486 administration and LH_2 and FSH_2 refer to patients having two bleeding episodes. No significant changes in LH were noted in either group. Analysis of variance detected a significant decrease in FSH_1 ($p < 0.001$) over the 48-hour sampling period.

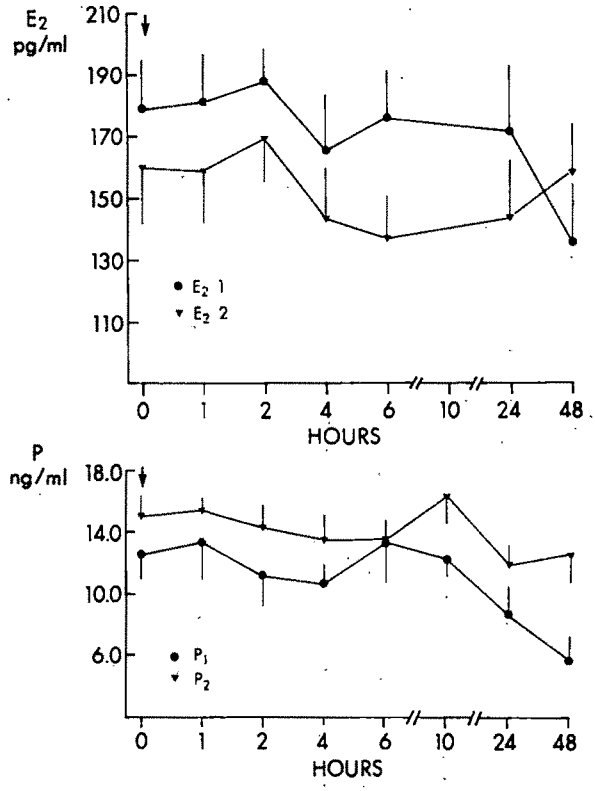

Fig. 2. *Upper panel*: Estradiol (E_2) values after a single oral dose of RU 486 ranging from 50 to 800 mg. $E_2 1$ refers to patients with one bleeding episode after RU 486 administration and $E_2 2$ refers to those with two bleeding episodes. Analysis of variance detected a significant decrease in $E_2 1$ ($p < 0.05$) over the 48-hour sampling period. *Lower panel*: Progesterone *(P)* values after a single oral dose of RU 486 ranging from 50 to 800 mg. P_1 refers to patients with one bleeding episode after RU 486 administration and P_2 refers to those with two bleeding episodes. Analysis of variance detected a significant decrease in P_1 ($p < 0.005$) over the 48-hour sampling period.

Subjects received either 50, 100, 200, 400, 600, or 800 mg of RU 486 (50 mg tablets supplied by Roussel-Uclaf, Romainville, France) at 8:00 AM. All groups comprised four subjects except for the two highest-dose schedules where five subjects were studied in each group. No smoking or food was permitted for 4 hours after ingestion of the medication and vital signs were recorded every 30 minutes for 6 hours. Blood samples were obtained through an indwelling catheter at −½, 0 +½, 1, 2, 4, 6, 10, 24, and 48 hours. A further group of five subjects received 200 mg as a single oral dose and blood sampling was continued daily for 1 week and then was performed at 10 and 14 days (extended sampling group).

These blood samples were assayed for prolactin, estradiol, progesterone, cortisol, LH, follicle-stimulating hormone (FSH), and RU 486 by previously described radioimmunoassay methods.[9-12] Normal serum AM cortisol values are 10 to 30 μg/dl. Two different radioimmunoassays were used to measure RU 486. The first was the method of Salmon and Mouren.[11] The second utilizes chromosorb column chromatography.[12] This latter, more specific assay was used only to measure RU 486 levels in the samples from the extended sampling group. The antiserum against RU 486 used in both assays was donated by Roussel-Uclaf. In addition, SMA-18 and complete blood count were performed at 0, 4, 10, 24, and 48 hours.

Results were analyzed by analysis of variance with the use of BMDP Statistical Software.[13] One- and two-way analysis of variance and Student's *t* test were used to determine statistical differences between groups.

Results

Clinical features. Menses commenced in all patients but one within 1 to 3 days after RU 486 administration (Table I). In nine of these 25 subjects (two who received 50 mg, two who received 100 mg, one who received 200 mg, one who received 400 mg, and three in the 800 mg group), this represented the only bleeding episode. The mean length of the treatment cycle in these nine subjects was significantly less ($p < 0.05$) than that of the following cycle (Table I).

In the remaining 16 subjects, a second bleeding episode was reported. In these subjects the initial bleeding episode occurred at a similar time after the LH surge as in the previous group, but the duration of bleeding was significantly shorter ($p < 0.05$). The full duration of the treatment cycle in those subjects who had two bleeding episodes (with the onset of the second bleeding episode used as a reference) was 32.9 ± 1.1 days. This was longer ($p < 0.05$) than the following cycle (Table I).

In none of these subjects were any adverse effects encountered. Furthermore, electrolytes, hepatic function, and blood count did not change in any subject. In one subject who received the 600 mg dose, bleeding did not occur until 56 days after treatment.

Hormonal parameters. The hormonal profiles of four patients (two from each group) were excluded from analysis because of incomplete data. In those 14 subjects who had two bleeding episodes, there was no change in serum LH, FSH, estradiol, or progesterone over the 48-hour sampling period. However, in those seven subjects who had a single bleeding episode, analysis of variance showed a significant decline in estradiol ($p < 0.05$), FSH ($p < 0.001$), and progesterone ($p < 0.005$) (Figs. 1 and 2).

There were no significant changes in LH, FSH, estradiol, or progesterone when hormonal results were expressed according to the dosage schedule of RU 486 and independent of the bleeding pattern. Analysis of variance showed that there was a significant increase in prolactin ($p < 0.05$) with the 50, 200, 400, and 800 mg dosages. When compared with the pretreatment levels, the peak values were greatest between 4 and 6 hours ($p < 0.05$). Values returned to normal by 24 hours (Fig. 3).

Analysis of variance showed a significant increase ($p < 0.05$) in mean cortisol values after the 100, 400, 600, and 800 mg doses. When compared with baseline values, the cortisol level rose significantly ($p < 0.05$) at 24 hours after the 600 and 800 mg doses and at 48 hours with all three higher doses (Fig. 4).

RU 486 levels. When measured directly after diethylether extraction, the serum levels of RU 486 reached a maximum between 1 and 4 hours after ingestion of all doses (Fig. 5). All RU 486 levels were significantly lower with the 50 mg dose than with the five higher-dose regimens ($p < 0.05$). The RU 486 levels at 6, 24, and 48 hours were also significantly lower after the 100 mg dose than with the four higher doses ($p < 0.05$). RU 486 levels were the same with doses of 200 to 800 mg. With doses of ≥200 mg, mean serum RU 486 levels fell minimally, and even after 48 hours values were still above 1.4 μg/ml. On the other hand, after the 50 and 100 mg doses, RU 486 values did decrease and were under 0.4 μg/ml at 48 hours. There were no differences in the RU 486 levels between the groups with one or two bleeding episodes.

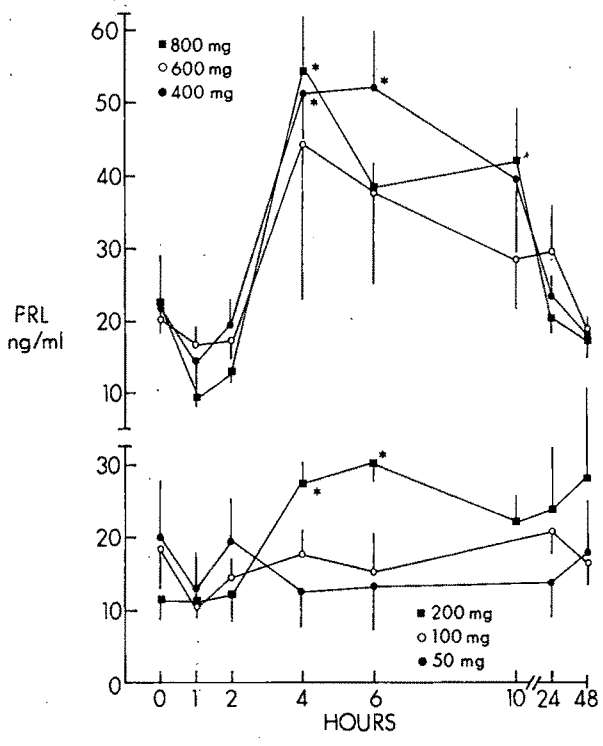

Fig. 3. Prolactin *(PRL)* levels after a single oral dose of RU 486 ranging from 50 to 800 mg. Analysis of variance detected a significant increase in *PRL* after the 50, 200, 400, and 800 mg doses, * $p < 0.05$ increase over baseline values as determined by the paired *t* test.

The serum levels of RU 486 in the extended sampling group are shown in Figs. 5 to 6. Chromosorb column chromatography was used in these samples and the values were lower than those with corresponding 200 mg dosage schedule. Nevertheless, after 4 hours the disappearance curves with both assays were parallel. Presumably, the values after chromatography represent true RU 486 concentrations. The half-disappearance time was 24 hours (Fig. 6).

Comment

Administration of RU 486 as a single oral dose from 50 to 800 mg in the early luteal phase was well tolerated. The induction of menses within 3 days is in accordance with results of previous studies.[5,6,15] This vaginal bleeding, which occurred despite high levels of estradiol and progesterone, implies that RU 486 acts directly on the endometrium to produce shedding regardless of any effect it may have on hormonal levels. A similar bleeding pattern has also been documented in nonpregnant women during concomitant treatment with RU 486 and human chorionic gonadotropin in the luteal phase.[6-14]

A total of 33% of our subjects displayed only a single

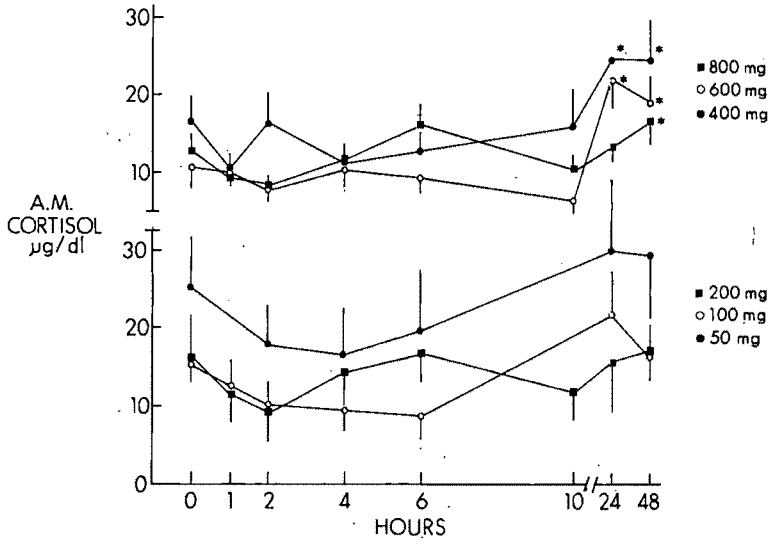

Fig. 4. Cortisol values after a single dose of RU 486 ranging from 50 to 800 mg. Analysis of variance detected a significant increase in cortisol ($p < 0.05$) after the 100, 400, 600, and 800 mg dose. * $p < 0.05$ increase over baseline values as determined by the paired t test.

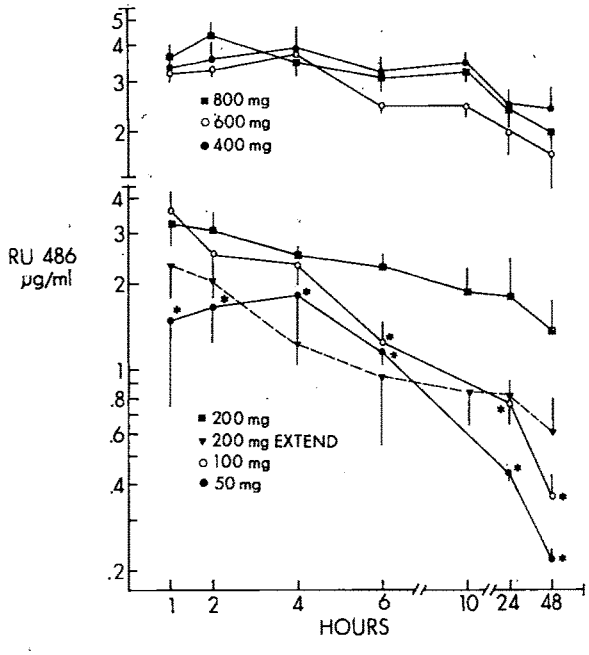

Fig. 5. RU 486 levels after a single oral dose of RU 486 ranging from 50 to 800 mg. Analysis of variance detected that all points after 50 mg dose and at 6, 24, and 48 hours after the 100 mg dose were significantly lower ($p < 0.05$) than values after the higher doses. The *200 mg extend* refers to the extended sampling group that is also depicted in Fig. 6.

bleeding episode, whereas in the remaining subjects a second bleeding episode occurred. This phenomenon appeared to be independent of the dose or serum concentration of RU 486. The hormonal profile in these two groups was distinctly different. In those subjects with two bleeding episodes there were no changes in LH, estradiol, or progesterone levels. In addition, if the commencement of the second bleeding episode is regarded as the termination of the cycle, the luteal phase appeared to be prolonged by RU 486. In contrast, in those subjects who had a single bleeding episode there was a progressive significant decline in serum FSH, estradiol, and progesterone levels over 48 hours of sampling time with a concomitant shortening of the luteal phase and cycle length. This suggests that under certain circumstances RU 486 can be luteolytic. Similar observations have been made by other workers.[6, 15] Although it is possible that the decline in steroid levels may represent the fall seen in the latter part of the normal menstrual cycle, this is unlikely since no corresponding fall occurred in the group with two bleeding episodes.

The decrease in the serum progesterone level could be related to a direct action of RU 486 on ovarian steroidogenesis.[17] However, it could also represent an effect on the hypothalamic-pituitary axis. We did observe a decrease in FSH in one group of patients but were unable to detect a decrease in LH secretion. Recently, with more frequent sampling we also observed a reduction in amplitude and frequency of LH pulses during RU 486 administration in the luteal phase.[18] Other workers have also described a reduction in LH pulse amplitude consequent to RU 486.[15]

Nieman et al.[6] observed menstrual bleeding in normal women within 72 hours of a single oral dose of RU 486 (10 mg/kg body weight) given in the midluteal phase. In the patients treated with RU 486 on luteal day 7, they report a decrease in the serum progesterone level by luteal phase day 10 and the onset of vaginal

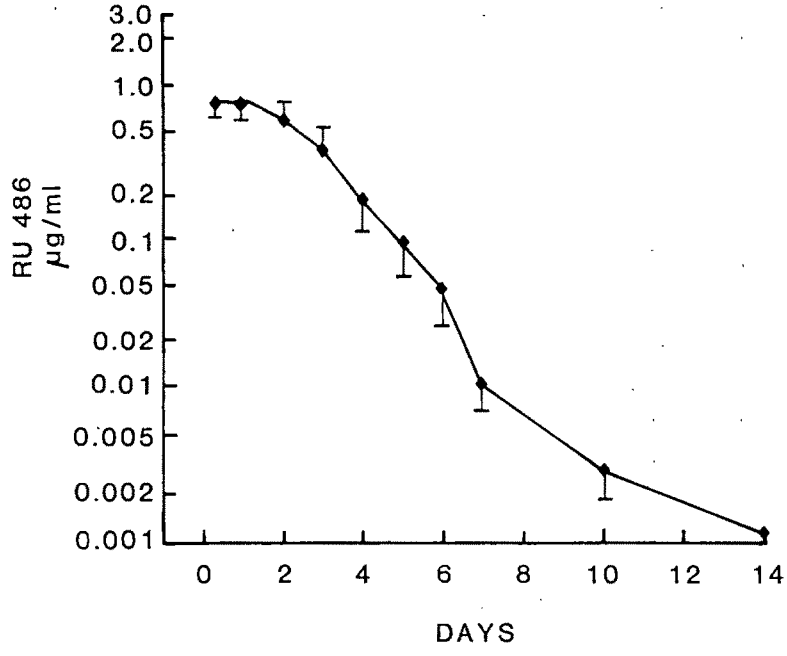

Fig. 6. RU 486 levels in the extended sampling group after a single oral dose of 200 mg RU 486. The half-life of RU 486 is 24 hours.

Table I. Effects of RU 486 administration

Bleeding episodes	*N*	*Onset (days after LH surge)*	*Days of bleeding*	*Treatment cycle length (days)*	*Posttreatment cycle length (days)*
1	9	9.8 ± 0.6	3.4 ± 0.3	25.2 ± 1.4*	34.0 ± 2.1
2	16	9.6 ± 0.5	6.0 ± 0.8†	32.9 ± 1.1	26.6 ± 1.7
		19.0 ± 0.8	4.2 ± 0.3		

Values are mean ± SD.
*$p < 0.05$ when compared with posttreatment cycle length.
†$p < 0.05$ when compared with group with one bleeding episode.

bleeding within 72 hours of treatment in all patients. They also described two patient groups as regards to the onset of menses, which may correlate with our two patient groups.

Circulating RU 486 levels measured by immunoassay showed that this synthetic steroid was absorbed rapidly. Doses of 50 and 100 mg gave lower blood levels than higher doses. However, no clear dose response was evident since 200 to 800 mg RU 486 gave similar blood levels. The immunoassay used to determine these circulating levels is nonspecific and measures metabolites, including the monodemethylated and didemethylated compounds as well as the alcoholic derivative.[11, 12] These metabolites seem to have a smaller biologic activity.[19] For this reason we developed a more specific radioimmunoassay using preliminary chromosorb chromatography. With this modification, values were lower but gave a parallel disappearance curve. Values of RU 486 measured by immunoassay after chromosorb chromatography give values similar to those determined by high-pressure liquid chromatography.[12] The half-life of RU 486 was 24 hours. The long half-disappearance of RU 486 suggests that there is binding to plasma proteins. Recent studies have shown that RU 486 binds to an α_1-globulin.[19]

The late rise in cortisol, noted at 24 and 48 hours after ingestion of the 400, 600, and 800 mg doses, suggests the presence of a mild degree of antiglucocorticoid activity with these doses. Nevertheless, mean values remained within the normal range. The late increase seen after 24 and 48 hours, without any change during the initial 10 daytime hours after ingestion of the drug, would be consistent with the work of Gaillard et al.,[3] who demonstrated that the antiglucocorticoid activity is seen only during the early morning hours when adrenocorticotropic hormone secretion is high.

Rakoff and Yen[16] reported a transient increase in prolactin in estrogen-primed women receiving in-

tramuscular progesterone after oophorectomy. This would imply a positive effect of progesterone on prolactin secretion, which is in contrast to the transient increase in prolactin we noted after treatment with an antiprogesterone. Healy et al.[20] described a decrease in prolactin after treatment with RU 486 in monkeys (10 mg/kg).[20] However, these were castrated monkeys who had steroid replacement via estradiol and progesterone capsules, which produce basal hyperprolactinemia. Within 1 hour after parenteral RU 486 administration, these elevated prolactin levels were decreased. Thus the effect of RU 486 on prolactin secretion varies and may depend on the mode of its administration, the dose, the species, and the prevailing steroid concentrations.

The reason why two subgroups emerged in this study is not evident. They could be differentiated by both bleeding patterns and hormonal levels. Both groups received RU 486 on days 6 to 8 after the LH surge and there were no differences in RU 486 serum levels between the two groups. Thus these two patterns of response could not be differentiated on the basis of time of treatment, dosage of RU 486, or circulating RU 486 levels.

RU 486 has been proposed as a once-a-month pill.[6] Our data would support the value of RU 486 for this use. However, the emergence of two patient groups suggests that further characterization of these distinctive patterns is necessary.

Effects of the antiprogesterone RU 486 in normal women

II. Administration in the late follicular phase

RU 486, a synthetic steroid with antiprogesterone receptor activity, was used to investigate the importance of progesterone on gonadotropin secretory dynamics in the midcycle of the normal menstrual cycle. Six normally cycling women were followed for three consecutive cycles. During each cycle, blood samples were obtained beginning on day 10 and continued until menses. After a control cycle, 100 mg RU 486 was given orally between days 10 and 17. The patients were followed for a posttreatment cycle with no medication. When RU 486 was given before the midcycle, the luteinizing hormone surge was delayed by 15.0 ± 2.1 days after ingestion of the last pill, resulting in cycles of 40.6 ± 2.6 compared with 28.0 ± 2.3 days ($p < 0.01$). During RU 486 administration and at the time a normal luteinizing hormone surge was anticipated, an attenuated luteinizing hormone/follicle-stimulating hormone surge was noted that was not followed by a rise in progesterone. After the attenuated surge a normal luteinizing hormone/follicle-stimulating hormone level occurred, with a normal rise in progesterone. Estradiol levels during RU 486 administration decreased during treatment, indicating a possible direct action of RU 486 on the ovary. (Am J Obstet Gynecol 1987;157:1421-6.)

Key words: RU 486, menstruation, gonadotropin

The precise mechanisms that underlie the processes of ovulation are not known, but two factors play important roles. The rapid rise of estrogen through a positive feedback action on the hypothalamic-pituitary unit triggers the midcycle surge. Also, the small increase in preovulatory progesterone levels[1] appears to amplify the pituitary secretion of luteinizing hormone (LH) and follicle-stimulating hormone (FSH) at midcycle.[2-4] RU 486, a synthetic steroid with antiprogesterone receptor activity,[5] was used to assess the importance of progesterone on midcycle secretory dynamics.

Material and methods

Six women ages 21 to 34 years with cycle length 28 ± 2 days were followed for 3 consecutive cycles. During each cycle, blood was drawn starting on day 10 and continued daily until the next menses. Bleeding records were kept during the study period. After the pretreatment cycle, 50 mg of RU 486 was administered twice a day (50 mg tablets supplied by Roussel-Uclaf, Romainville, France) from day 10 through 17. The selection of this dose was based on a dose-response study.[6] During the posttreatment cycle the patient received no medication, but blood sampling continued as in the two previous cycles.

Blood samples were allowed to clot and sera were separated and stored at −20° C until assayed for LH, FSH, estradiol (E_2), and progesterone by previously reported radioimmunoassay.[7-9] Computer assistance by Clinfo program and BMDP Statistical Software[10] was used for statistical analysis with area under the curve, the Kruskal-Wallis nonparametric test, the paired t test, and one- and two-way analysis of variance when appropriate. The area under the curve was determined by the trapezoidal rule and included values on days −2 through +2 after the LH surge for determination of LH and FSH, days −2 through 0 for E_2, and days 0 through +14 for progesterone.

Results

Administration of RU 486 during the late follicular phase delayed development of a normal LH surge an average of 15.0 ± 2.1 days from the time of the last tablet (range 10 to 21 days). This resulted in a follicular phase of 28.0 ± 2.3 days, which was significantly longer than the follicular phase in the control cycle of 14.6 ± 1.3 days ($p < 0.005$). During the treatment

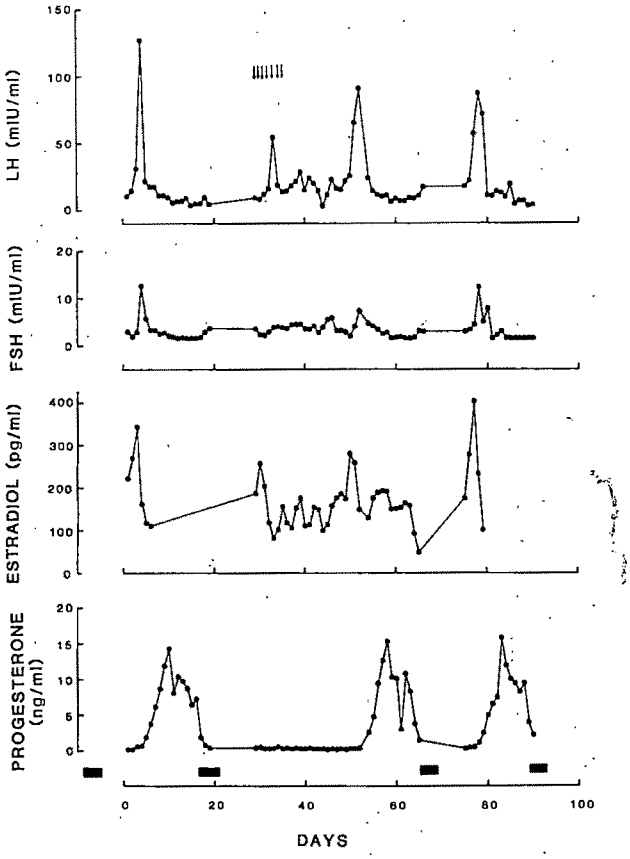

Fig. 1. LH, FSH, and progesterone values over the 3-month study period in a typical patient. *Arrows* indicate treatment days and *solid bars* indicate bleeding days. An attenuated surge occurs during the time of RU 486 administration and is followed by a normal LH surge.

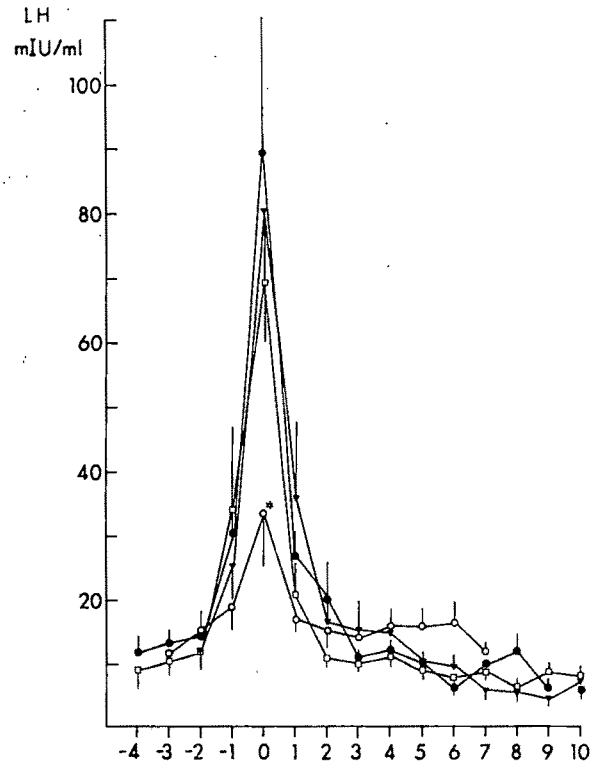

Fig. 2. LH values normalized to the day of the LH surge during the pretreatment month (▼) the attenuated (○) and normal (●) surges after RU 486 treatment, and the posttreatment cycle (□). The values of the attenuated surge are significantly lower on day 0 than before treatment ($p < 0.05$).

month, the interval between the normal LH surge and the occurrence of menses was 13.8 ± 1.2 days and not different from the pretreatment luteal phase length. The total treatment cycle length after RU 486 administration averaged 40.6 ± 2.6 days, compared with 28.0 ± 2.3 days during the pretreatment cycle ($p < 0.01$; Table I).

The bleeding pattern and serum LH, FSH, progesterone, and E_2 values of a representative subject are shown in Fig. 1. In the pretreatment cycle shortly after blood sampling began, the normal LH surge was followed by a rise in serum progesterone levels compatible with a normal luteal phase pattern. The length of this subject's pretreatment cycle was 29 days. During the following cycle RU 486 was administered during days 10 through 17. On day 14 into the treatment cycle, and during the time an LH surge was expected, an attenuated LH surge was noted that was smaller than the normal LH surge of the pretreatment cycle and was not followed by any rise in progesterone levels.

Nineteen days after the attenuated surge, a normal LH surge was noted that was followed by a rise in serum progesterone compatible with a normal luteal phase. There was no vaginal bleeding between the time of the attenuated surge and the treatment normal surge. The next bleeding episode occurred after the fall in serum progesterone, and this resulted in a total cycle length for the treatment cycle of 49 days. During the posttreatment cycle, a normal LH surge occurred on day 13 and the total cycle length was 26 days. All six patients demonstrated similar patterns.

Fig. 2 shows the mean (±SEM) LH values for all six patients normalized to the day of the LH surge (day 0). The LH surge of the pretreatment cycle, the treatment normal surge, and the surge during the posttreatment cycle are similar in magnitude. However, the attenuated surge occurring during RU 486 administration was significantly less. Kruskal-Wallis one-way analysis of variance detected LH values on day 0 to be significantly lower than control values ($p < 0.05$). These data were also confirmed by calculation of areas under the LH curve (Fig. 3).

Similar data for FSH are shown in Figs. 3 and 4. Values of FSH on days 0 and +1 were significantly smaller ($p < 0.001$) during the attenuated surge com-

pared with pretreatment values as determined by one- and two-way analyses of variance. Calculation of the areas under the FSH curves also confirmed these findings (Fig. 3).

E_2 values normalized to the day of the LH surge are shown in Fig. 5. When taken together, values on days -1 and 0 were significantly less ($p < 0.005$) than pretreatment values. Areas under the curve for E_2 during the attenuated surge were significantly less than the pretreatment, normal treatment, and posttreatment surge values.

Fig. 6 shows the progesterone values normalized to the day of the LH surge. Progesterone values preceding the attenuated surge were significantly lower ($p < 0.01$) on days -1 and 0 compared with pretreatment and posttreatment values when analyzed by analysis of variance. Progesterone levels from days 1 through 8 after the attenuated LH surge were also significantly lower ($p < 0.01$) than pretreatment values. However, once a normal LH surge occurred after RU 486, it was followed by a normal rise in progesterone during the next 14 days. The total area under the progesterone curve after the treatment normal surge was not different from the values after the pretreatment or posttreatment surges, whereas the area under the curve after the attenuated surge was significantly less ($p < 0.01$).

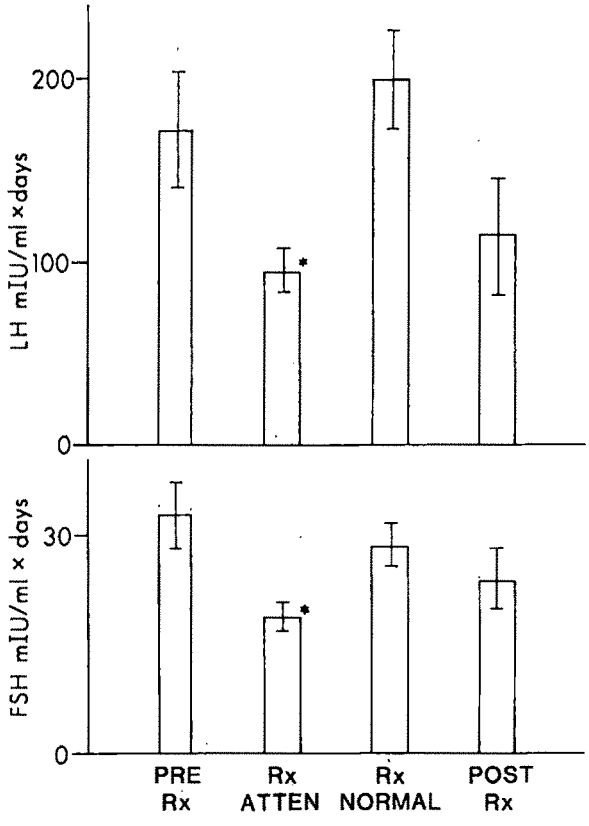

Fig. 3. Areas under the LH and FSH curve in the pretreatment month *(PRE-Rx)*, during the attenuated LH surge *(Rx ATTEN)*, in the normal LH surge occurring during the RU 486 treatment cycle *(Rx NORMAL)*, and in the posttreatment month *(POST Rx)*. $*p < 0.05$.

Comment

Administration of RU 486 during days 10 through 17 of a normal menstrual cycle prevented the development of a normal LH/FSH surge and delayed formation of a new surge by an average of 15 days. This confirms the ability of RU 486 to effectively block the midcycle gonadotropin surge, delay follicular development, and prolong menstrual cycle length.[11-14] This effect is most probably related to its antiprogesterone activity and not its antiglucocorticoid activity, as this effect is not altered by concomitant administration of dexamethasone in primates.[13] Our data support the possibility that progesterone antagonism affects the hypothalamic-pituitary axis by inhibiting the normal positive effect of progesterone on gonadotropin secretory dynamics at midcycle. RU 486 has been reported to have a mild progestational effect, and similar to the suppressive effect of progestins in oral contraceptives, the effect of RU 486 on midcycle gonadotropin may be due to progesterone agonism.[13] However, the dominant effect of RU 486 is that of an antiprogesterone, and it is more likely that suppression of the LH surge is due to progesterone antagonism.

In addition, there was a significant reduction in E_2 and progesterone levels before the day of the attenuated LH/FSH surge. These data suggest that RU 486 may have a direct inhibitory effect on ovarian steroidogenesis. In vitro studies support a direct action of RU 486 on ovarian E_2 and progesterone production.[15, 16] However, it may also be the case that lower FSH levels inadequately stimulate ovarian E_2 production. A decline in FSH levels after RU 486 was noted in this study and in other studies.[6]

The 15-day delay from the time of the last tablet to the onset of a normal LH surge suggests that recruitment of another dominant follicle is required to initiate ovulation after what appears to be ablation of the dominant follicle by RU 486 administration. This is supported by recent ultrasonographic studies of follicular development after RU 486.[14] However, it is plausible that the dominant follicle may not be ablated as such and may merely be arrested temporarily and undergo spontaneous recovery after RU 486 administration ceases. Further ultrasonographic studies may better characterize follicular development.

Successful blockage of the LH/FSH surge has been reported in humans[11] and in monkeys[12, 13] when treated in the late follicular phase. These data confirm the abil-

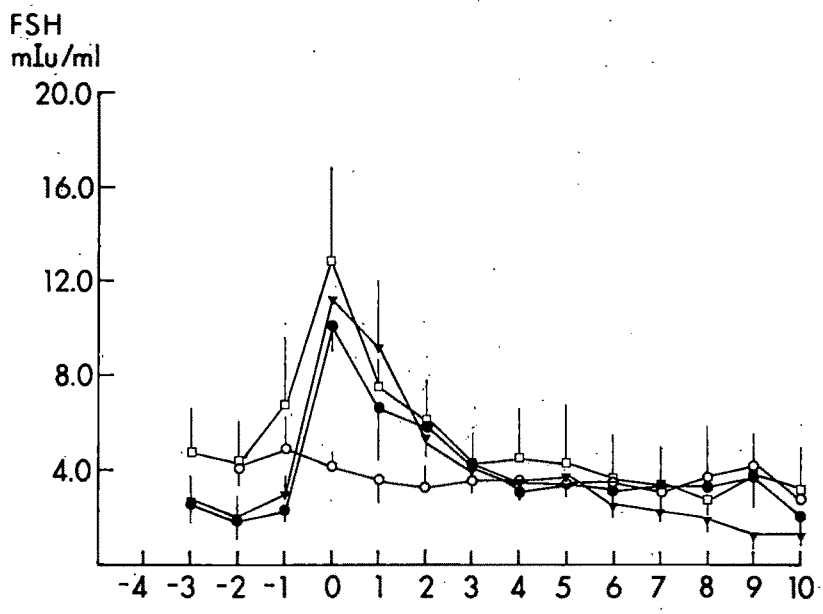

Fig. 4. FSH values normalized to the day of the LH surge during the pretreatment month (▼) the attenuated (○) and normal (●) surges after RU 486 treatment, and the posttreatment cycle (□). FSH values on days 0 and +1 were significantly less ($p < 0.001$) during RU 486 treatment than before treatment.

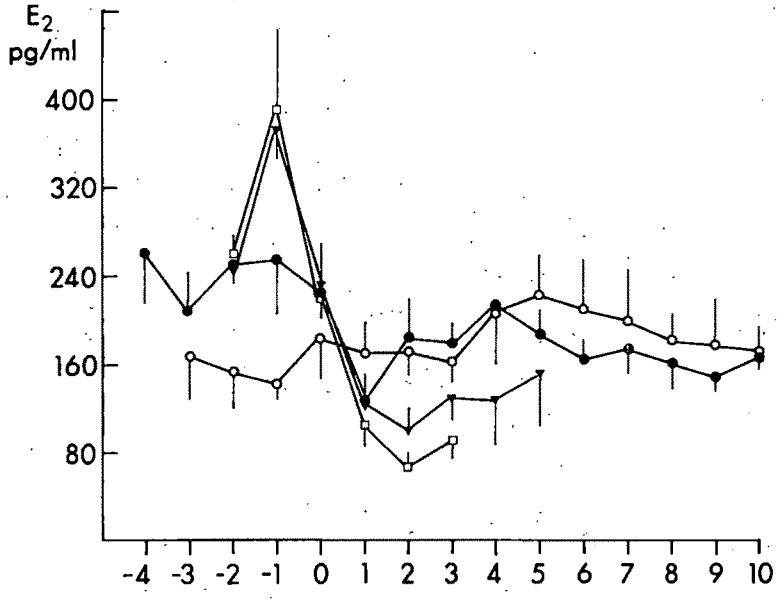

Fig. 5. E_2 values normalized to the day of the LH surge during the pretreatment month (▼), the attenuated (○) and normal (●) surges after RU 486 treatment, and the posttreatment cycle (□). E_2 values on days −2, −1, and 0 were significantly less ($p < 0.005$) during the attenuated response than at any other time.

ity of RU 486 to suppress the midcycle LH/FSH surge and support its development as a contraceptive agent. However, whether the mechanism for this action of RU 486 is primarily due to its suppressive effect on the ovary[11, 15, 16] or to progesterone antagonism at the hypothalamic-pituitary axis will require further study.

Serum CA-125 in the evaluation of benign adnexal cysts

Donald E. Pittaway, M.D., Ph.D., Jamil A. Fayez, M.D., and James W. Douglas, M.D.
Winston-Salem, North Carolina

Because serum CA-125 concentrations are increased in women with endometriosis, our objective was to determine whether CA-125 levels could be used to differentiate endometriotic from nonendometriotic beign cysts. During a 2-year period, all women who had an endometrioma (n = 33) or a nonendometriotic cyst (n = 27) that was ≥4 cm were included. Serum CA-125 levels were measured by an immunoradiometric assay, and the mean concentrations in women with an endometriotic cyst increased as the diameter of the cyst increased. The mean CA-125 concentrations in women with cysts ≥4 cm were 53 ± 2 U/ml in 19 women with an endometriotic cyst, 11 ± 1 U/ml in 20 women with a nonendometriotic cyst, and 15 ± 1 U/ml in 7 women with a nonendometriotic cyst and endometriosis. In the fluid of 10 endometriomas, the mean CA-125 concentration was 290 ± 94 × 10^3 U/ml (range 10 to 900 × 10^3 U/ml). With cysts diameters ≥4 cm, 19 of 19 women with endometriotic cysts, zero of seven women with nonendometriotic cysts and endometriosis, and zero of 20 women with nonendometriotic cysts had CA-125 concentrations ≥20 U/ml (99% upper normal limit). We conclude that serum CA-125 determinations offer an excellent method to differentiate endometriotic from nonendometriotic benign cysts. (Am J Obstet Gynecol 1987;157:1426-8.)

Key words: CA-125, ovarian cysts, endometriosis

Adnexal cysts are frequently encountered during the reproductive years. Because most are nonneoplastic functional ovarian cysts, a period of observation is the customary approach when the cyst is less than 6 to 8 cm.[1,2] However, 10% to 35% of benign cystic adnexal masses may be an endometrioma.[1,3] Because endometriomas are not likely to resolve spontaneously, and may enlarge or rupture during the period of observation, a test to detect an endometrioma would assist in the evaluation and management of adnexal cysts. Since serum CA-125 concentrations are elevated in endometriosis,[4,5] we evaluated the serum test to determine whether CA-125 levels could differentiate endometriotic from nonendometriotic cysts.

Material and methods

Preoperative serum samples were obtained from 60 women of reproductive age (median 28 years; range 13 to 42 years) between 7 to 10 days after the last menses.[6] The women were undergoing laparoscopy or laparotomy for evaluation of a cystic adenxal mass (n = 19) or infertility (n = 41), and informed consent was obtained for evaluation of serum CA-125. When the type of cyst was in question at laparoscopy, a 1 cm biopsy specimen of the cyst wall was obtained for histologic diagnosis. The size of the cysts was determined by direct comparison with a probe calibrated in centimeters. All women with an endometrioma or a nonendometriotic cyst that was ≥4 cm were included. In women (n = 5) who had more than one endometrioma, the diameters were added and the total diameter was correlated with the CA-125 concentration.

CA-125 was measured in the serum samples and endometriotic cyst fluid by an immunoradiometric assay (Centocor, Malvern, Penn.) as previously described.[5] Fisher's exact test and Student's t test with a log transformation when necessary were used to analyze the data.

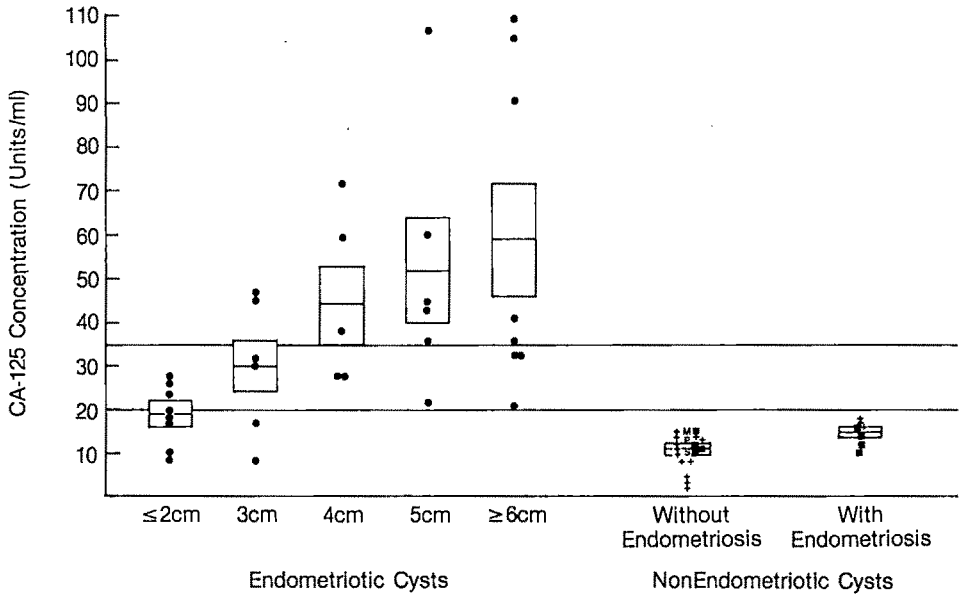

Fig. 1. Serum CA-125 concentrations in endometriotic cysts (by diameter) and nonendometriotic cysts (≥4 cm). The nonendometriotic cysts include follicular (+), corpus luteum (■), serous (*S*), mucinous (*M*), and paratubal (*P*).

Results

Serum CA-125 concentrations increased with increasing size of the endometriotic cyst (Fig. 1). The mean (±SEM) CA-125 concentrations by the total diameter of the endometriotic cyst were: ≤2 cm, 19 ± 3 U/ml; 3 cm, 30 ± 6 U/ml; 4 cm, 44 ± 9 U/ml; 6 cm, 52 ± 2 U/ml; and ≥6 cm, 59 ± 13 U/ml. The types of nonendometriotic cysts included serous (one), mucinous (one), paratubal (one), corpus luteum (nine), and follicular (15); the corresponding serum CA-125 levels for nonendometriotic cysts and nonendometriotic cysts with endometriosis are also shown in Fig. 1. The mean (±SEM) CA-125 concentrations in women with cysts ≥4 cm were 53 ± 12 U/ml in 19 women with endometriotic cysts, 11 ± 1 U/ml in 20 women with nonendometriotic cysts, and 15 ± 1 U/ml in seven women with nonendometriotic cysts and endometriosis. When the fluid in 10 of the endometriotic cysts was analyzed for CA-125, the mean (±SEM) level was 290 ± 94 × 10^3 U/ml (range 10 to 900 × 10^3 U/ml).

With cyst diameters ≥4 cm (Table I), all 19 women with endometriotic cysts, zero of 20 women with nonendometriotic cysts, and zero of seven women with nonendometriotic cysts and endometriosis had serum CA-125 concentrations ≥20 U/ml, which is the 99% upper limit of normal in our assay. In addition, 13 of 19 women (60%) with endometriotic cysts that were ≥4 cm had CA-125 concentrations >35 U/ml, and five of 19 women (26%) had concentrations >65 U/ml.

Comment

Endometriotic cysts have been shown to be a source of elevations in serum CA-125 levels. This finding has two implications in the clinical management of a woman with an adnexal cyst. First, women with endometriotic cysts ≥4 cm have serum levels of CA-125 that are often >35 U/ml. Because CA-125 concentrations > 35 U/ml suggest epithelial ovarian cancer for which the serum test was developed,[7,8] endometriotic cysts are a significant source of false-positive determinations in the preoperative screening for epithelial ovarian cancer, and vice versa. In one study investigating adnexal cystic masses, approximately 10% of the women had an endometrioma and about 2% had ovarian cancer.[5] Second, in women with adnexal cysts ≥4 cm, serum CA-125 concentrations <20 U/ml are compatible with

a nonendometriotic cyst. Consequently, serum CA-125 determinations offer an excellent method to differentiate endometriotic from benign nonendometriotic cysts. In the young woman of reproductive age with a cystic adnexal mass, a CA-125 level <20 U/ml would support a period of expectant management, and with levels >20 U/ml and particularly >35 U/ml, the possibility of an endometrioma, and at the higher level the possibility of an endometrioma or epithelial ovarian cancer, would require further diagnostic investigation by laparoscopy or laparotomy.

Although the ability to differentiate an endometriotic cyst from benign nonendometriotic cysts was 100% in this study at the 20 U/ml level, it is anticipated that false-positive results with respect to endometriotic cysts will occur. We have observed CA-125 levels ≥20 U/ml in women with endometriosis without an endometrioma,[5] and it would be possible for a similar patient to have a nonendometriotic cyst. Serum CA-125 levels are increased and roughly double during menses,[6] so that care should be taken to avoid obtaining blood samples during menstruation. Also, approximately 9% of women with chronic pelvic inflammatory disease have CA-125 levels >20 U/ml,[5] so that a hydrosalpinx or a tubo-ovarian complex may occasionally have associated elevated levels. Furthermore, early pregnancy and acute pelvic infections frequently result in elevated CA-125 concentrations,[5] although these conditions most often can be differentiated on a clinical and laboratory basis.

We have demonstrated that the use of serum CA-125 level determinations can provide useful information in the evaluation of women with an adnexal cyst. Elevations in CA-125 levels would support proceeding with a laparoscopy or laparotomy to diagnose, stage, and individualize therapy for either endometriosis or, more rarely, ovarian cancer. On the other hand, a CA-125 level <20 U/ml provides reassurance that observation of the cyst is appropriate, and that an endometriotic cyst that may enlarge or rupture during the period of observation is unlikely.

HLA antigen expression and induction by γ-interferon in cultured human trophoblasts

Michael A. Feinman, M.D., Harvey J. Kliman, M.D., Ph.D., and Elliott K. Main, M.D.

Philadelphia, Pennsylvania, and Bronx, New York

The expression and regulation of HLA antigens were examined in isolated human trophoblasts. Immunocytochemical studies that used monoclonal antibodies against class I (HLA-A, B, and C) antigens revealed that both cytotrophoblasts and syncytiotrophoblasts can express HLA heavy chains and β_2-microglobulin. Expression of these antigens increased with time in culture. The addition of recombinant γ-interferon (1000 U/ml) to the cultures significantly increased cellular staining for these antigens over controls throughout the 72-hour time course studied. In addition, we noted that gene expression for HLA class I heavy chain was also markedly augmented by the addition of γ-interferon. Expression of class II (HLA-DR) antigens was not detected in any of the experiments. These results suggest that during in vitro differentiation, cytotrophoblasts can express class I HLA antigens and the genes controlling their production can be regulated. Alterations in the expression or suppression of these antigens during pregnancy could be responsible for some pregnancy complications. (Am J Obstet Gynecol 1987;157:1429-34.)

Key words: HLA antigen, γ-interferon, human trophoblasts, major histocompatibility complex

The products of conception represent a tissue allograft that normally escapes rejection. One approach to explain this phenomemon has focused on the altered expression of major histocompatibility complex antigens on fetal and chorionic tissues. The two categories of major histocompatibility complex antigens most important for immune responses are class I, which are critical as recognition sites for cytotoxic T-lymphocytes, and class II, which are intimately involved in immunoregulation. For humans, class I antigens are the HLA-A, B, and C molecules, which are invariably associated with the monomorphic light-chain, β_2-microglobulin. Class II antigens are the HLA-DR, DP, and DQ molecules. Major histocompatibility complex antigens do not appear to be present on villous syncytiotrophoblasts or cytotrophoblasts in intact villous placental tissue.[1-6] In contrast, some class I antigens have been detected in nonvillous trophoblasts cells[2] and early proliferating cytotrophoblasts.[3] However, there has been a fairly uniform failure to demonstrate the presence of class II antigens such as DR in any trophoblast population.[4-6] Clinically we know that the mother is exposed to these antigens at some point in gestation because of the presence of anti-HLA antibodies in some primigravid and many multiparous women and by the demonstration of anti-idiotypic antibodies in normal pregnant women.[7] Further evidence that these antigens could be expressed in gestation is derived from studies of HLA gene regulation in trophoblast-lineage cells. Genes coding from major histocompatibility complex antigens appear to remain accessible and hence regulatable. Specifically, γ-interferon has been shown to enhance expression of class I major histocompatibility complex antigens in choriocarcinoma cells[8] and human amnion cells.[9]

Kliman et al.[10] recently described a technique of isolating cytotrophoblasts from term human placentas. In culture these cells aggregate and fuse to form syncytiotrophoblasts and exhibit endocrine functions typical of this multinucleated cell layer (e.g., production of human chorionic gonadotrophin, progesterone, and human placental lactogen). Electron microscopic and immunocytochemical studies have shown that the freshly isolated cells represent at least a 95% pure population of cytotrophoblasts.[10] In addition, Main et al.[11] have previously analyzed the surface antigen expression of this population using indirect immunofluorescence and found that 5% express either T cell or macrophage markers.

This in vitro model has already been useful for studying the relationship between differentiation of cytotrophoblasts and endocrine regulation.[12] Therefore we used this culture system to study the immunobiology of trophoblasts. Specifically, we addressed two questions. First, can isolated trophoblasts exhibit major his-

tocompatibility complex antigens in vitro? Second, can expression of these antigens and genes be upregulated by γ-interferon, a known inducer of major histocompatibility complex expression? Because β_2-microglobulin could be expressed with other class I–like molecules, it is important to examine expression of both β_2-microglobulin and HLA heavy chains.

Material and methods

Cytotrophoblasts were isolated from term placentas obtained immediately after delivery. Villous tissue was serially digested with trypsin and deoxyribonuclease, and the resulting cells were placed on a Percoll gradient, as previously described in detail.[10] Suspensions of 0.5 ml containing 500,000 cells were plated on glass coverslips.[10] In some experiments, recombinant human γ-interferon (a generous gift of Genentech, South San Francisco, California) was added to the medium to a final concentration of 1000 U/ml. In some other experiments, 8-bromo-cyclic adenosine monophosphate (Sigma Chemical Co., St. Louis, Missouri) was also added at the time of plating (to a final concentration of 1.5 mmol/L).

Immunocytochemical studies that used an avidin-biotin immunoperoxidase system (Vector Laboratories, Burlingame, California) were performed as described in earlier papers.[10, 13] Monoclonal antibodies to HLA heavy chain (W6/32) and β_2-microglobulin (L368) (both gifts of Dr. L. Lampson, University of Pennsylvania, Philadelphia, Pennsylvania) were used at 1:5 dilutions of hybridoma culture supernatant. Monoclonal antibodies to Dr were used at varying dilutions up to a maximum of 1:2 (OKIa, Ortho Pharmaceutical Co.). Rabbit antibodies against the α-subunit of human chorionic gonadotropin were used at 1:1000 dilutions to confirm the morphologic findings of trophoblasts (gift from Drs. Canfield and Birken, Columbia Medical Center, New York). Negative control hybridoma supernatants and nonimmune rabbit serum were used in each experiment as previously described.[10, 11]

To quantitate the results, 500 nuclei were counted in multiple random fields at each separate time point (4, 12, 24, 48, and 72 hours from culture initiation). The proportions of cells present as single cells, aggregates, and syncytia were calculated. In addition, the percentage of each cell type staining for a specific antigen at each time point was also calculated.

Ribonucleic acid (RNA) was isolated by suspending cultured cells in 4 mol/L guanidinium isothiocyanate followed by ultracentrifugation over a cesium chloride cushion. The 10 μg of each sample underwent electrophoresis through a 1% agarose gel containing 1X MOPS buffer, 6% formaldehyde, and 0.5 μg/ml of ethidium bromide. Using standard Northern blot procedure, the RNA was transferred to Gene Screen Plus membrane (Dupont). After baking in vacuo, the membrane was prehybridized overnight in a solution containing 50% formamide, 1 mol/L sodium chloride, 50 mmol/L Tris, pH 7.4, 1% sodium dodecyl sulfate, 0.5 μg/ml of heparin, 1X Denhardt's solution, 250 μg/ml of salmon sperm deoxyribonucleic acid (DNA), and 10% dextran sulfate. Hybridization with a ^{32}P–Nick-translated cDNA probe for HLA heavy chain (courtesy of S. Weissman, Yale University)[14] was performed in the same buffer for 24 hours. Filters were then exposed for 3 to 24 hours with Kodak XRP film. Scanning densitometry was performed with a LKB ultrascan.

Statistical analysis of the data used χ^2 analysis for comparing the proportions of cells with positive antibody staining at each time point with and without recombinant human γ-interferon treatment. For analysis of change in HLA antigen expression over the time course in culture, we used the Mann-Whitney U test.[15] All studies were conducted with full Human Studies Committee approval.

Results

Under our in vitro conditions, human trophoblasts can express the class I antigens β_2-microglobulin and HLA heavy chain (W/632) (Fig. 1). Immunocytochemical localization of these class I antigens demonstrated that cultured trophoblasts express these proteins between 24 and 72 hours of culture and that recombinant human γ-interferon induced an increased expression of these molecules. In contrast, immunocytochemistry failed to demonstrate staining for Ia in these cultured trophoblasts whether in the presence or absence of recombinant human γ-interferon (data not shown). The few macrophages present (usually under 2% and always under 5%) in these preparations served as internal positive controls for the antibodies examined (Fig. 1, *a* and *g*).

Quantitation of the immunocytochemical studies yielded the results shown in Figs. 2 and 3. Fig. 2 shows the results of immunocytochemical staining for HLA heavy chains (W6/32). In *panel A*, we note the proportion of each cell type present in culture over time. As previously seen, a shift from single cells to syncytia occurred over 72 hours.[10] At 72 hours, the major cell form was the syncytiotrophoblast. The normal morphologic differentiation of the trophoblasts was not affected by recombinant human γ-interferon. Therefore these results represent the average of both the recombinant human γ-interferon treated and untreated cells. We examined the expression over time of HLA heavy chains in the absence or presence of recombinant hu-

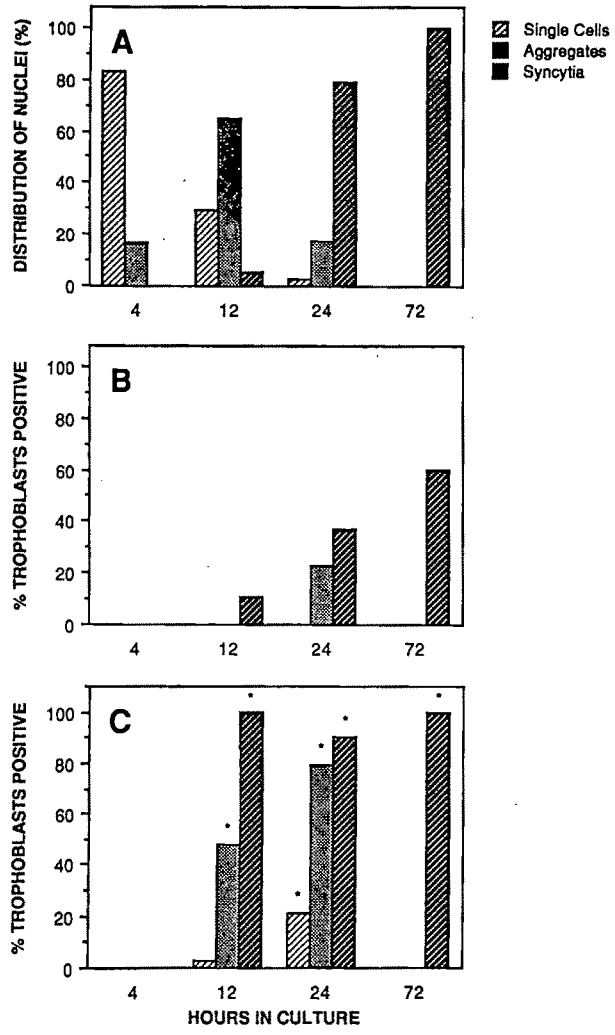

Fig. 2. Quantification of trophoblast morphology **(A)** and immunocytochemical staining for HLA heavy chain (W6/32) in the absence **(B)** and presence **(C)** of γ-interferon. Purified human cytotrophoblasts were cultured for as long as 72 hours as described in the Material and Methods section. **A,** Five hundred nuclei were counted at each time point, and the percentage of single cells, aggregates, and syncytia were calculated. At 4 hours the dominant cell type was the single cell. Aggregates were dominant at 12 hours, whereas syncytia were most prevalent at 72 hours. Treatment with γ-interferon did not affect this progression. **B,** In the absence of γ-interferon, expression of class I heavy chains was first noted at 12 hours in syncytia. At 24 hours, both syncytia and aggregates showed staining. At 72 hours, 60% of the trophoblasts (now all syncytia) stained for the antigen. **C,** In the presence of 1000 U/ml of recombinant human γ-interferon, there was a significant ($p < 0.001$, denoted by *asterisk*) increase in staining for all cell types at all times except for single cells at 12 hours. As shown in Fig. 1, *g-h,* the intensity of the cellular staining also increased.

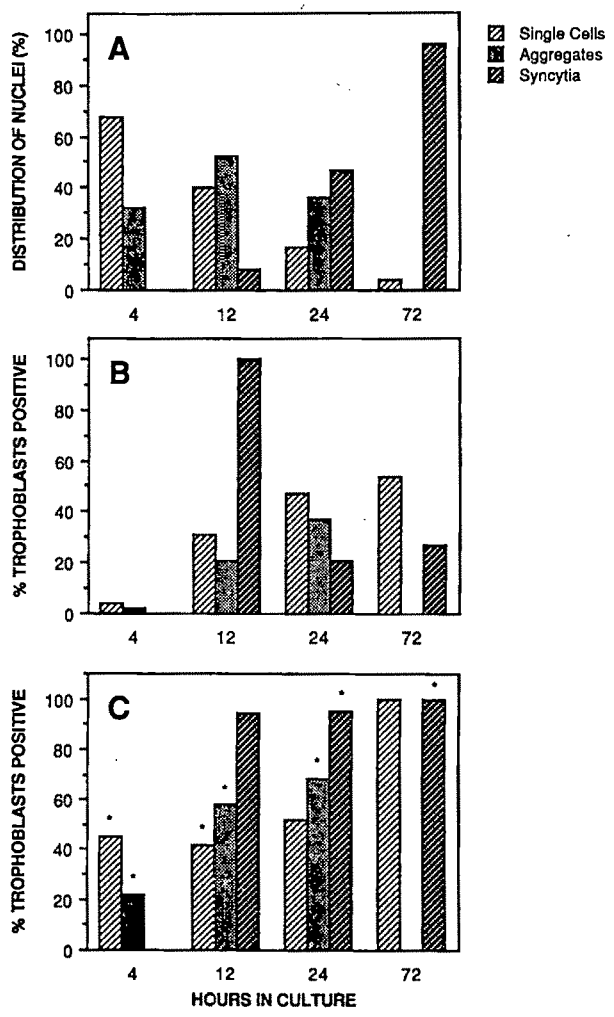

Fig. 3. Quantification of trophoblast morphology **(A)** and immunocytochemical staining for β_2-microglobulin (L368) in the absence **(B)** and presence **(C)** of γ-interferon. Purified human cytotrophoblasts were cultured for as long as 72 hours as described in the Material and Methods section. **A,** Trophoblast forms were calculated as described in the legend to Fig. 2. The progression of trophoblast forms was quite similar to that in Fig. 2. **B,** In the absence of γ-interferon, β_2-microglobulin was detected as early as 4 hours and tended to increase over time. At 72 hours, when syncytia dominated, only 27% of these cells contained detectable levels of β_2-microglobulin. **C,** In the presence of 1000 U/ml of recombinant human γ-interferon, there was a significant ($p < 0.001$, denoted by *asterisk*) increase in the percentage of cells staining for β_2-microglobulin at all time points examined (except for syncytia at 12 hours and single cells at 24 and 72 hours where these forms made up only 8%, 17%, and 4% of the trophoblasts, respectively). In addition to an increase in the percentage of cells staining, γ-interferon induced an increase in intensity of cell staining (Fig. 1, *a-f*).

man γ-interferon. Fig. 2, *B* demonstrates the production of these proteins in the control (untreated) cells. By 12 hours, a few aggregates exhibited the HLA heavy chains. During the next 36 hours, there was a gradual increase in appearance of these molecules, so that at 72 hours, 60% of syncytiotrophoblasts showed light cytoplasmic staining by the antibody. This change over time was significant at the $p < 0.0001$ level. Expression of HLA heavy chains was greatly increased by the ad-

dition of recombinant human γ-interferon, as shown in Fig. 2, *C*. Virtually all the syncytia were strongly stained after 12 hours. Aggregates showed a significant increase in percentage staining at 12 and 24 hours. Even though only a few single cells were counted at 24 hours, there was a significant increase in percentage staining. Significant ($p < 0.001$, χ^2) increases in percentage staining is denoted by an *asterisk* above the bars in Figs. 2 and 3.

Similar experiments were performed that examined the expression of β_2-microglobulin. Fig. 3, *A* shows the proportion of each cell type present at each time point. Fig. 2, *B* shows the fraction of each cell type staining for β_2-microglobulin in the control group. Although a few positive cells were seen at 4 hours, significant staining was first seen at 12 hours. Roughly 20% to 40% of the cells had the molecule. As shown in Fig. 3, *C*, recombinant human γ-interferon greatly enhanced the expression of β_2-microglobulin. Changes were not significant in instances in which few cells were present of a certain type. These experiments were repeated on three occasions, of which all produced similar results. In contrast to its effects on trophoblast hormone production, the addition of 8-bromo-cyclic adenosine monophosphate did not affect the expression of either HLA heavy chains or β_2-microglobulin (data not shown).

Fig. 4 represents a Northern transfer blot demonstrating the presence of class I heavy chain mRNA in unstimulated trophoblasts after 48 hours of culture. Treatment with recombinant human γ-interferon for 24 hours appeared to augment expression of the HLA message. These findings have been replicated three times.

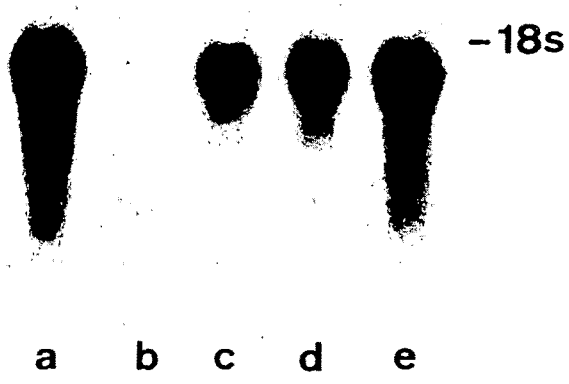

Fig. 4. The γ-interferon augments trophoblast expression of class I heavy-chain mRNA. Isolated mRNA from 8866 (lane a), K562 (lane b), trophoblasts without interferon (lane c), trophoblasts with 4 hours of treatment (lane d), and trophoblasts with 24 hours of 1000 U/ml recombinant human γ-interferon treatment (lane e) underwent electrophoresis, Northern transfer, and hybridization with a ^{32}P–labeled cDNA probe for class I heavy-chain as described in the Material and Methods section. The 8866, a B cell line, serves as the positive control whereas K562, an erythroleukemic line, is the negative control. All the trophoblasts were harvested at 48 hours after culture initiation. By scanning densitometry, lane e (24-hour treatment) represents a 1.8-fold increase over lanes c and d.

Comment

Using a purified cell culture of isolated cytotrophoblasts, we have shown that during differentiation, trophoblasts can express class I major histocompatibility complex molecules. As in other studies, we could not demonstrate expression of class II antigens. The addition of recombinant human γ-interferon greatly enhanced the expression of class I major histocompatibility complex antigens both in terms of intensity of staining and the number of cells staining for HLA heavy chain (W6/32) and β_2-microglobulin (L368). Furthermore, RNA analysis confirms these immunohistochemical findings by demonstrating measurable class I mRNA in unstimulated trophoblasts cultured for 48 hours and induction of this mRNA in the presence of recombinant human γ-interferon. Thus the genes coding for class I molecules are not irreversibly downregulated in isolated trophoblasts. These results imply that control of HLA expression in intact villi may be by another process.

Recently, Hunt et al.[16] reported an inability to induce HLA antigen expression by purified γ-interferon in tissue explants derived from first- and third-trimester placentas.[16] There are several reasonable explanations for the differing results between these findings and ours. First, Hunt et al. examined tissue explants with intact villi that may possess the ability to downregulate HLA expression. We used cytotrophoblasts removed from the chorionic villi, thus possibly freeing them from this inhibition. Second, by definition, any placental explant experiments use well-differentiated syncytiotrophoblasts. Our cell culture system allows us to study cytotrophoblasts as they differentiate in culture. The expression of HLA antigens may occur very early in gestation as syncytia form.

We have previously demonstrated that cytotrophoblasts in culture functionally differentiate and assume endocrine functions typical of syncytiotrophoblasts. This process is enhanced by 8-bromo-cyclic adenosine monophosphate.[12] In contrast, the addition of

8-bromo-cyclic adenosine monophosphate did not affect expression of HLA antigens.

These results suggest that differentiating trophoblasts are capable of expressing class I major histocompatibility complex antigens. The following are several possible explanations for the absence of these proteins in the intact placenta: (1) The production of these antigens may be suppressed in normal pregnancy by local or maternal factors; (2) the antigens may be lost as the villous syncytia mature; or alternatively, (3) the cells may produce HLA antigens, but are induced to shed them before or as soon as they are incorporated into the membrane.

Since recombinant human γ-interferon enhanced expression of class I major histocompatibility complex antigens, it may be useful to see if there is an increased expression of these proteins in pathologic conditions. This could explain the possible but unproved relationship between infections and habitual abortions. Potentially, interference with mechanisms that downregulate the expression of these antigens may also account for other pregnancy complications.

Finally, we feel that the purified cell culture system used in this study will prove to be a useful model to help us understand how the products of conception attain their immunologically protected status. Contrasting results between studies that use cell cultures and intact tissue preparations could help identify which factors play a role in this important process.

We thank Ms. Catherine Aversa for her excellent technical assistance.

Cerebrospinal fluid levels of magnesium in patients with preeclampsia after treatment with intravenous magnesium sulfate: A preliminary report

Gary R. Thurnau, M.D., David B. Kemp, M.D., and Anthony Jarvis, M.B., B.Ch.
Oklahoma City, Oklahoma

The purpose of this study is twofold: (1) to correlate magnesium levels of serum with those of cerebrospinal fluid in patients with preeclampsia receiving intravenous magnesium sulfate, and (2) to determine whether the magnesium ion crosses the blood-brain barrier in significant amounts after intravenous magnesium sulfate therapy. Of the 21 patients in whom spinal anesthesia was used for delivery, ten patients with preeclampsia with therapeutic serum magnesium levels made up the study group and 11 term nontreated normotensive gravid women served as controls. At the time of spinal anesthesia, a 1 ml aliquot of cerebrospinal fluid was obtained from each patient. The mean cerebrospinal fluid magnesium level for the control group was 2.56 ± 0.19 mg/dl (range 2.2 to 2.8 mg/dl). For the preeclamptic group who received intravenous magnesium sulfate, the mean cerebrospinal fluid magnesium level was 3.04 ± 0.12 mg/dl (range 2.9 to 3.2 mg/dl). Although only a small amount of magnesium crosses the blood-brain barrier after intravenous magnesium sulfate treatment, this increment is highly significant ($p < 0.001$). (Am J Obstet Gynecol 1987;157:1435-8.)

Key words: Cerebrospinal fluid, magnesium sulfate, preeclampsia, blood-brain barrier

The incidence of eclamptic seizures is extremely low after parenteral magnesium sulfate ($MgSO_4$) therapy of the patient with preeclampsia.[1, 2] However, the unresolved question is: Does magnesium (Mg^{++}) cross the blood-brain barrier in significant amounts and provide a central nervous system site of action after parenteral $MgSO_4$ therapy? Despite previous studies[3-6] on this issue, controversy continues with regard to the site of action of $MgSO_4$ in the prevention and treatment of eclamptic convulsions.[7, 8] Furthermore, no investigator has proved that the small increment in cerebrospinal fluid Mg^{++} levels after intravenous $MgSO_4$ treatment of preeclampsia-eclampsia is either statistically significant or related to dose and time.

The purpose of our study is twofold: (1) to correlate serum magnesium levels with those of cerebrospinal fluid in patients with preeclampsia who receive $MgSO_4$, and (2) to determine whether Mg^{++} crosses the blood-brain barrier in significant amounts after intravenous $MgSO_4$ therapy.

Methods

The sample population consisted of 21 gravid women in whom spinal anesthesia was used for delivery. Eleven normotensive gravid women served as controls, of which nine were delivered by cesarean section and two by low forceps after saddle blocks. The study group consisted of ten gravid women with preeclampsia according to classic criteria[9] for whom intravenous $MgSO_4$ treatment was started at least 4½ hours before delivery (range 4½ to 72 hours). Of these, five were delivered by cesarean section and five were delivered by low forceps after saddle blocks.

Patients without a contraindication to spinal anesthesia were prospectively entered into the study after giving informed consent. For those patients with preeclampsia, intravenous $MgSO_4$ was administered in the following manner: a 6 gm loading dose was given over 15 to 20 minutes, followed by a 2 gm/hr maintenance dose.

In all patients, a lumbar puncture was performed with a 25 gauge 3½ inch needle and cerebrospinal fluid flow was confirmed in all four quadrants. A 1 ml aliquot was then obtained by dependent drainage, after which Xylocaine spinal anesthesia was administered. Simultaneously, a venipuncture was performed to acquire a 3 ml aliquot of serum for Mg^{++} assay.

Assays of cerebrospinal fluid and serum Mg^{++} were performed by means of an automatic clinical analyzer magnesium method, which is a modification of the methylthymol blue complexometric procedure.[10]

Results

Individual descriptive and outcome variables for the sample population are given in Table I.

The mean (±SD) serum Mg^{++} level for the control group was 1.44 ± 0.16 mg/dl (range 1.2 to 1.8 mg/dl). For the preeclamptic group, the mean serum Mg^{++} level was 5.53 ± 0.87 mg/dl (range 4.2 to 6.8 mg/dl). As shown in Table II, the mean serum Mg^{++} level of the group receiving intravenous $MgSO_4$ is significantly higher than that of the untreated control group ($p < 0.001$).

The mean cerebrospinal fluid (±SD) magnesium level for the control group was 2.56 ± 0.19 mg/dl (range 2.2 to 2.8 mg/dl). For the group with preeclampsia who received intravenous $MgSO_4$, the mean cerebrospinal fluid Mg^{++} level was 3.04 ± 0.12 mg/dl (range 2.9 to 3.2 mg/dl). When compared with the untreated control group, the mean cerebrospinal fluid Mg^{++} level was significantly higher in the group treated with intravenous $MgSO_4$ ($p < 0.001$). Furthermore, no overlap of the cerebrospinal fluid Mg^{++} levels was observed between the two groups (Table II).

Next, CSF Mg^{++} levels *(y)* were plotted as a function of serum Mg^{++} levels *(x)* and regression analysis was performed (Fig. 1). Regression analysis of the control group produced the following regression equation: $y = 1.40 + 0.808x$ ($r = 0.689$). Regression analysis of the group treated with intravenous $MgSO_4$ produced the following regression equation: $y = 2.35 + 0.125x$ ($r = 0.925$). Although the regression lines for both groups in Fig. 1 are extended beyond the range of their respective values, theoretic extrapolations are not implied.

Comment

In 1955 Pritchard[3] evaluated magnesium levels in plasma and cerebrospinal fluid of 10 preeclamptic-eclamptic patients treated with intramuscular $MgSO_4$. Although he found cerebrospinal fluid Mg^{++} levels to be slightly higher in the $MgSO_4$-treated group (2.65 versus 2.35 mEq/L), he made two conclusions: (1) an equilibrium between plasma Mg^{++} (3.0 to 8.0 mEq/L for 3 to 48 hours) and cerebrospinal fluid Mg^{++} (average = 2.65 mEq/L) was never obtained, and (2) the cerebrospinal fluid level of Mg^{++} is not dependent on the plasma level. Although plasma and cerebrospinal fluid magnesium levels in our patients are similar to

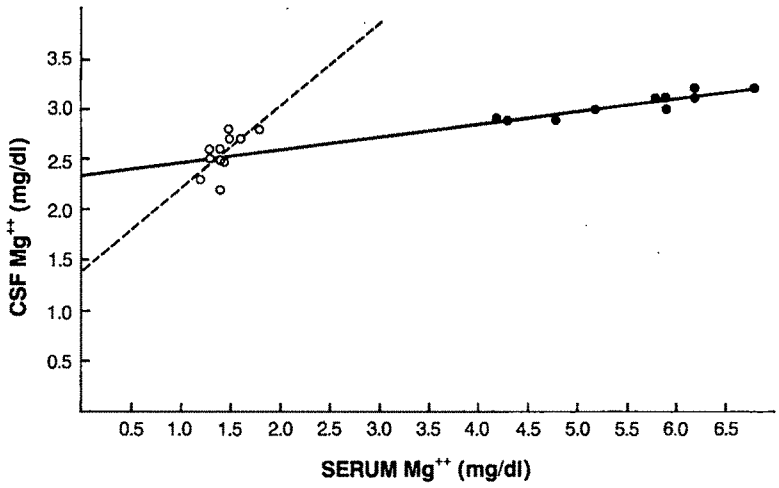

Fig. 1. Relationship between cerebrospinal fluid (*CSF*; y) and serum (x) Mg^{++} levels. *Open circles* represent the nontreated normotensive control subjects, and *closed circles* represent the preeclamptic gravid women who received intravenous $MgSO_4$. Regression equations: Controls, $y = 1.40 + 0.808x$ ($r = 0.689$); patients with preeclampsia, $y = 2.35 + 0.125x$ ($r = 0.925$).

those of Pritchard's, our conclusions are opposite of his. Statistical analysis of the small but statistically significant increment of cerebrospinal fluid Mg^{++} in the treated group may be the explanation.

Oppelt[4] in 1963 evaluated Mg^{++} levels in plasma and cerebrospinal fluid of 29 mongrel dogs treated with intravenous $MgSO_4$. He found that Mg^{++} crossed the blood-brain barrier in small but significant amounts, and speculated that it may be influenced by an active transport mechanism. He concluded that the appearance of a significant increase of Mg^{++} in the cerebrospinal fluid may be a time-related phenomenon.

Somjen[5] in 1968 investigated the ability of intrathecally administered Mg^{++} to depress excited target neurons in the cerebral cortex of 11 cats anesthetized with pentobarbital sodium. He demonstrated that Mg^{++} significantly reduces the electrical discharge frequency in cortical neurons. He concluded that a relatively small increment in cerebrospinal fluid Mg^{++} concentration has a significant depressant effect on cortical function.

In 1978 Borges[6] studied the effect of intravenous $MgSO_4$ on the electroencephalographic patterns of 10 anesthetized cats with *n*-penicillamine–induced seizures. As the plasma Mg^{++} levels increased, he observed an associated decrease in cortical firing. He speculated that the degree of central nervous system depression secondary to increased plasma Mg^{++} levels was dose and time dependent.

Despite the findings of these studies, over the past 30 years three questions have remained unresolved: (1) After intravenous $MgSO_4$ therapy, does Mg^{++} cross the blood-brain barrier in significant amounts? (2) Does an increment in cerebrospinal fluid Mg^{++} provide a central nervous system site of action? (3) Is the cerebrospinal fluid Mg^{++} increment observed in $MgSO_4$-treated patients simply correlated to the serum Mg^{++} level, or is it related to dose and time? Because the appearance of a significant increment of Mg^{++} in the cerebrospinal fluid may be a dose- and time-related phenomenon influenced by an active transport mechanism,[4] we designed this preliminary study to evaluate cerebrospinal fluid Mg^{++} levels after at least 4½ hours of intravenous $MgSO_4$ treatment.

Based on these preliminary data, we believe that cerebrospinal fluid Mg^{++} levels *(y)* are highly correlated with serum Mg^{++} levels *(x)* in patients treated with intravenous $MgSO_4$ (regression equation: $y = 2.35 + 0.125x$; $r = 0.925$). Although only a small amount of Mg^{++} crosses the blood-brain barrier after at least 4½ hours of intravenous $MgSO_4$ therapy, we found this increment to be highly statistically significant ($p < 0.001$).

Despite our findings, two questions remain unanswered: (1) What is the minimum $MgSO_4$ dose and minimum treatment interval that will provide a significant cerebrospinal fluid Mg^{++} concentration increment? (2) Does an elevated CSF Mg^{++} level reflect a central nervous system site of action?

To address these two issues, further studies are currently underway. The answers to these two questions may explain Chesley and Tepper's observation of eclamptic seizures that occasionally occur in preeclamptic patients with confirmed "therapeutic serum levels" of Mg^{++} after parenteral $MgSO_4$ therapy.[11]

Effects of cochlear ablation on local cerebral glucose utilization in fetal sheep

Robert M. Abrams, Ph.D., Alastair A. Hutchison, M.B., Ch.B., Michael J. McTiernan, B.S., and Gerald E. Merwin, M.D.
Gainesville, Florida

Local cerebral glucose utilization was measured by the [^{14}C]-deoxyglucose method in five near-term fetal sheep in whom bilateral ablation of the cochleae had been accomplished aseptically 5 to 8 days earlier. The tympanic membrane and ossicles were removed and all turns of each cochlea were unroofed with destruction carried to the modiolus. Mean local cerebral glucose utilization of 33 of 34 gray matter structures and four of four white matter structures in operated animals were significantly lower ($p < 0.05$) than that in unoperated control fetuses. The depression in local cerebral glucose utilization was greatest ($p < 0.002$) in brain stem auditory nuclei, in which the mean rate of glucose utilization was approximately 25% of the levels in unoperated fetuses. The pattern of glucose utilization in these structures was clearly altered, with a reversal of the normal distribution in density of the inferior colliculus. Tonotopic bands of high local cerebral glucose utilization frequently seen in autoradiographs of inferior colliculus in unoperated fetuses were not observed in operated fetuses. These results show that the glucose utilization of the brain, and by implication the normal growth and maturation of the brain, depends on an intact auditory system during prenatal life. (Am J Obstet Gynecol 1987;157:1438-42.)

Key words: Fetal sheep, local cerebral glucose utilization, brain stem, auditory nuclei, cochlear ablation

Environmental sounds are known to penetrate the abdominal wall and uterus of pregnant women. Specific sounds can induce fetal movements[1, 2] and cardioacceleration,[3-5] reduce fetal breathing movements,[1] and evoke fetal electroencephalographic responses.[6] There have been speculations about the importance of sound in prenatal nervous system maturation,[7] imprinting,[8] and early neonatal speech recognition.[9] Fetal cochlear damage may result if noise is excessive.[10] Thus prenatal sound may have far-reaching implications for the developing child.

The constraints placed on human experimentation force us to turn to appropriate animals to further our understanding in this area of developmental bioacoustics. As a model for human characteristics, the pregnant sheep has two advantages over common laboratory animals: (1) the physical dimensions (and thus the acoustic properties) of the ewe and her products of conception, including fetal fluids, are similar to those in human pregnancy, and (2) the cochlea and central auditory connections are anatomically completed and presumed functional by the third trimester of gestation in both species.[11, 12] An important first step in our understanding of this model, the characterization of the fetal sound

environment within the pregnant ewe, has already been made.[13-15] Thus a 2 to 5 dB enhancement within the ewe for frequencies <0.25 kHz was found; frequencies >0.25 kHz were progressively attenuated up to 20 dB at 4.0 kHz; external speech and music were easily recognizable, albeit muffled, once the noise floor (50 dB spectrum level) was exceeded.

While these results proved that the fetal sound environment is richer and more varied than heretofore believed,[13] the specific effects of sound on the fetus are less accessible to quantitative assessment, and are therefore sometimes inconsistent.[4, 7] One consistent finding, however, is the high rate of glucose utilization along the central auditory pathways of the fetus in utero.[16] The origins of this high metabolic rate for glucose, which is also present in animals after birth,[17-20] has not been established. The present study was undertaken to determine the importance of the cochlea in sustaining this high rate of local cerebral glucose utilization in the fetal sheep.

Methods

Ten grade Western ewes with known dates of insemination were fasted for 24 hours, anesthetized with halothane by mask, intubated, and carried throughout an aseptic surgery with halothane and oxygen. The fetal head was located through the uterine wall and moved to a relatively avascular area on the greater curvature. With the head held firmly by one hand, the uterine serosa, but not underlying tissues, was incised over 4 inches. Small openings in the myometrium and membranes were made, and these tissues were then stretched to the extent of the serosal incision. This procedure resulted in little bleeding. The fetal head and one foreleg were delivered. Polyvinyl catheters were placed in the fetal brachiocephalic artery and superior vena cava through incisions in the axillary artery and a superficial shoulder vein.

In five experimental animals, we used an operating microscope to remove the tympanic membrane and ossicles, working through a postauricular approach. Oval and round windows were identified. With the aid of round cutting burs, all turns of the cochlea were unroofed, with destruction carried to the modiolus.

After completion of three ablation experiments, it was brought to our attention that fetal cerebral oxygen consumption rates and local cerebral glucose utilization rates were correlated with the behavioral state of the fetus at the time of the experiment.[21, 22] Thus in five control animals and two of five experimental animals, stainless steel screws (0-80; 1/8 in) were placed bilaterally in parietal bone 1 to 2 cm on either side of the midline cranial suture. Additional screws (0-80; 1/4 in) were placed through predrilled holes in the roof of the orbit. Stranded tinned copper lead wires, previously silver soldered to the screws, were led out through the scalp and skin incisions. Wire electrodes (Cooner Wire Company, Chatsworth, Calif.) placed on a neck strap muscle completed the instrumentation required for assessment of fetal behavioral state.

All fetal skin incisions were closed. Ampicillin, 0.5 gm, was introduced in the amniotic fluid. The fetal

*Destruction versus controls.

head and foreleg were repositioned in the uterus and the uterus was closed. A second dose of 0.5 gm ampicillin was placed in the peritoneal cavity of the ewe before the anterior abdominal wall was closed. Leads were tunneled subcutaneously and exited on the maternal flank, where they were stored in a pouch sutured to the skin. The skin was closed with clips. Finally, maternal femoral arterial and venous catheters were placed. Anesthetic levels were reduced during the closing procedure so that the ewe stood within 5 minutes of extubation.

Ewes were placed in carts daily to flush catheters. A cart containing a companion ewe was positioned nearby. On the day of the local cerebral glucose utilization experiment (3 to 8 days after surgery), the fetal behavioral state was assessed during a 2-hour control period (Table I).

Details of the method used to measure cerebral glucose utilization have been published.[16] Briefly, 100 μCi [^{14}C]-2-deoxyglucose (American Radiolabeled Chemicals, St. Louis, Mo.) per kilogram of estimated fetal weight were given over 30 seconds. The histories of the arterial plasma levels of [^{14}C]-2-deoxyglucose and glucose were determined by frequent blood sampling for 30 to 40 minutes. Fetuses and ewes were given intravenous sodium pentobarbital solution followed immediately by intravenous KCl to induce cardiac arrest. The fetus was delivered and weighed and the brain was removed and frozen for later sectioning and quantitative autoradiographic examination.[16]

Local cerebral glucose utilization was calculated for 38 cerebral structures. Means and SEM of values for experimental and control groups were calculated across structures. Comparisons between groups were by

paired Student's t test with significance taken as $p < 0.05$. The average rate of glucose utilization for the entire brain was not measured.

Results

Gross inspection of the fetal temporal bones removed after the study revealed that the cochleae were destroyed bilaterally to the level of the modiolus.

Table I summarizes data for both experimental and control fetuses. Fetal weights, pH, $PaCO_2$, PaO_2, and glucose levels were within the range of those characteristic of our flock.[16] Local cerebral glucose utilization in experimental fetuses was uniformly depressed, with 33 of 34 gray matter structures and four of four white matter structures differing significantly ($p < 0.05$) from respective structures in control fetuses (Table II). Reduction in local cerebral glucose utilization in the four brain stem auditory nuclei (cochlear nuclei, superior olives, lateral lemniscus, and inferior colliculus) reached even higher levels of significance ($p < 0.002$). The pattern of glucose utilization in the inferior colliculus as represented pictorially in autoradiographs was clearly altered, with the appearance of a very pale central nucleus and a denser periphery.

Behavioral state cycling during the 30 to 40 minutes required to measure local cerebral glucose utilization appeared to be normal in two operated fetuses, and the quality of the electrocorticogram, electrooculogram, and neck electromyographic tracings was good.

Comment

The [^{14}C]-2-deoxyglucose method of Sokoloff et al.[23] offers a powerful method of metabolic encephalography. As seen consistently on autoradiographs, the brain structures with the highest concentrations of [^{14}C] (and thus with the highest glucose utilization rates) are the cochlear nuclei, superior olives, lateral lemnisci, and inferior colliculi—all structures in the central auditory pathway. Audiographs of the inferior colliculi are characterized by differing densities, with the darkest area occupying part or all of the central nucleus. This dark region, whose metabolic rate normally exceeds that of all other loci in the brain, commonly takes on the shape of an ovoid or band. Other bands, presumably representative of a tonotopic, spacial organization of frequency coding,[18-20] are occasionally seen.

These autoradiographic features have been observed by us in all normal fetal sheep. We inferred that the high rates of glucose utilization in central auditory structures could be at least partly related to environmental sound that is continuously present.[13-15] The sound originates outside the ewe as well as within the ewe, through intestinal, cardiovascular, and respiratory activities and through vocalization. Intra-amniotic pressure changes resulting from pulsation of the umbilical artery could be an additional source of sound. Because of the well-known link between local functional activity and local metabolic rate in the brain,[17] ambient noise intense enough to evoke fetal cardioacceleration and movement would be expected to activate the metabolism along the auditory pathways. The specificity of this metabolic response, depending as it must on the maturation of the central auditory pathways and connections, would be more advanced in sheep fetuses than in term fetuses of less precocious species.

Bilateral destruction of the fetal cochleae resulted in a dramatic reduction in glucose utilization in the central auditory nuclei. This phenomenon has been well documented postnatally in animals.[17, 24, 25] We did not explore the effects of unilateral destruction, but this procedure has been used to judge the levels and extent of crossing of afferent auditory fibers.[25]

A decrease in glucose utilization in nonauditory structures in operated fetuses was not anticipated, and has not been mentioned previously in descriptions of cochlear ablation in animals postnatally. Virtually all gray and white matter structures were affected to a significant extent. In earlier experiments in fetal sheep, glucose utilization was found to be relatively high in brain stem auditory structures at the beginning of the third trimester.[16] Thus central auditory projection to nonauditory structures, including the reticular formation, would appear early and could dominate the representation of other sensory modalities that have yet to mature to the same degree. Continuing with this reasoning, removal of the cochleae could result in a diffuse inactivation of the central nervous system, which would be reflected in its lowered metabolic rate. The reduction could be linked to the elimination of any transduction of acoustic energy by the destroyed cochleae as well as to the removal of spontaneous, resting neural discharge of auditory neurons.[20] The possibility must also be considered that the overall reduction in cerebral glucose utilization may have resulted from the generalized trauma associated with the destructive lesioning. However, the technique used in bilateral cochlear destruction was entirely peripheral, without violation of dura or intracranial vasculature or contents. While microcontamination of cerebrospinal fluid via a patent cochlear aqueduct is possible, the effects of such blood contamination must be considered minimal. Whatever the cause of the lowered cerebral metabolic rate, it may have some consequences for normal maturation of the fetal brain.

We thank Drs. K. J. Gerhardt and Jack Johnson for helpful comments on the manuscript, the Lesly Martin and Sue Laing for manuscript preparation.

Umbilical artery flow velocity waveforms and placental resistance: The effects of embolization of the umbilical circulation

Brian J. Trudinger, M.D., Denise Stevens, B.Sc., Anita Connelly, B.Sc., J. Robert S. Hales, Ph.D., George Alexander, D.Sc., Laurence Bradley, B.Sc., Alan Fawcett, B.Sc., and Rosemary S. Thompson, Ph.D.

Westmead and Prospect, New South Wales, Australia

Embolization of the umbilical placental circulation in fetal lambs was carried out to occlude the small vessels of the placental vascular bed and to observe the effect on the umbilical artery flow and flow velocity waveforms. Thirteen singleton fetuses were studied from day 120 of pregnancy. Embolization was achieved by injecting approximately 9×10^6 microspheres of 15 μm diameter into the fetal placental cotyledons along the umbilical arteries over 9 days. Umbilical and uterine flows were measured by radioactive microsphere counting. The umbilical placental resistance was increased (0.25 to 0.35 mm Hg · ml · min^{-1}) by embolization, and there was an increase in the umbilical artery systolic/diastolic ratio. Embolization produced a significant fall in umbilical flow expressed either as total flow (312 to 237 ml · min^{-1}) or when normalized by reference against splanchnic flow (3.36 to 1.53). We conclude that the umbilical artery flow velocity waveform systolic/diastolic ratio measures the reflection coefficient at the peripheral vascular bed (the "resistance vessels") of the placenta. (Am J Obstet Gynecol 1987;157:1443-8.)

Key words: Umbilical blood flow, flow velocity waveforms, embolization, Doppler ultrasound

Studies of umbilical artery flow velocity waveforms in normal human pregnancy[1] indicate a pattern of high diastolic flow velocity (point B) relative to the systolic peak velocity (point A) (low A/B or peak systolic to least diastolic ratio). With advancing gestational age the ratio of peak systolic to least diastolic velocity (A/B) decreases. This pattern has been assumed to be due to the low resistance of this vascular bed. Umbilical circulation resistance has been directly measured in ovine pregnancy[2,3] and found to decrease with increasing gestational age.

The umbilical artery velocity waveform pattern is quite different in situations of antenatal fetal compromise, as indicated by subsequent birth of a small for gestational age infant. The diastolic flow velocity (B) is low relative to the systolic peak velocity (A), so that the systolic/diastolic (A/B) ratio is high.[1,4,5] A placental microvascular correlative study has demonstrated a loss of small arteries in the tertiary villi of the placentae of human patients exhibiting a high systolic/diastolic (A/B) velocity ratio.[6] The loss of these vessels would be expected to increase resistance, because they are the resistance vessels of the fetal placental circulation.

Our purpose was to examine the relationship between umbilical artery flow velocity waveforms and both volume blood flow and resistance in the umbilical circulation of sheep. Experimental alteration in resistance was produced by a technique of microsphere embolization of the fetal umbilical cotyledonary circulation. Embolization of the ovine maternal uteroplacental circulation with microspheres has been used to alter resistance and decrease flow[7-10] to provide an experimental model of fetal growth retardation. Embolization of the umbilical placental circulation has not been previously reported.

Material and methods

Preparation of animals. Thirteen ewes of known mating date were surgically prepared between days 115 and 120 of gestation. The ewes were fasted for 24 hours before the operation. Anesthesia was induced with 1 gm of thiopental, the ewe was intubated, and anesthesia was maintained by inhalation of a nitrous oxide/oxygen with fluothane mixture. All surgery was done by use of an aseptic technique. The uterus was first exposed by a midline incision, the fetal lamb was palpated, and a small incision was made in the uterus

*$p < 0.05$ in comparison to control observation.

to allow delivery of a hind limb. Polyvinyl catheters were inserted into the fetal aorta via the femoral artery (catheter inside diameter 1.0 mm, outside diameter 1.5 mm, inserted to 10 cm) and into the fetal inferior vena cava via a leg vein (catheter inside diameter 1.0 mm, outside diameter 2.0 mm, inserted to 20 cm). Intra-amniotic catheters (inside diameter 1.5 mm, outside diameter 2.5 mm) were also inserted and attached to the fetal buttock. Catheter locations were confirmed after the death of the fetus. The fetal membranes and uterine incision were closed in two layers. The fetal catheters were filled with heparinized saline solution (25,000 μ in 500 ml) and plugged. They were exteriorized by a flank incision over which a holding pouch was sewn. A polyethylene catheter (inside diameter 1.0 mm, outside diameter 1.5 mm) was also inserted into the left common carotid artery of the ewe and guided down to the apex of the left ventricle under radiologic visualization. Another polyethylene catheter (inside diameter 1.0 mm, outside diameter 1.5 mm) was inserted into one of the saphenous arteries of the ewe and advanced 15 cm to the femoral artery. Maternal catheters were kept in a neck pouch and hind limb pouch, respectively.

The ewe was given procaine penicillin, and streptomycin, 750 mg each, at the time of surgery and daily for the next 3 days. The fetal lamb was given intramuscular cloxacillin (125 mg) at surgery and intravenous penicillin (150 mg) and streptomycin sulfate (100 mg) daily for the next 3 days. All fetal catheters were flushed with heparinized saline solution daily, while the maternal catheters were flushed every second day.

The animals were maintained in metabolic stalls after surgery. They were allowed water ad libitum and fed 1200 gm of 60% lucerne chaff/40% oats in pellet form daily. All studies were conducted with the ewe standing.

Measurements

Blood flow. Radioactive-labeled 15 μm microspheres (New England Nuclear Company, Boston, Mass.) were used to measure maternal and fetal blood flows.[11] The microspheres were labeled with chromium 51, tin 113, ruthenium 103, strontium 85, niobium 95, and scandium 46. Specific activity ranged from 2.5 to 50 counts per microsphere. The sequence in which these were used on the three occasions and whether to ewe or fetus was randomized. Before injection, the microspheres were mixed by an ultrasonicator. Each fetal flow estimation was carried out with approximately 1×10^6 microspheres injected into the inferior vena cava catheter and flushed over 20 seconds. A blood reference sample was taken from the lower fetal aorta by a withdrawal pump over 1 minute (8 ml) beginning just before the injection and ending 30 seconds after the injection was completed. Maternal flow was estimated by injecting at least 20 million microspheres into the left ventricle and taking a 30 ml reference sample over 1.5 minutes from the femoral artery. The location of the ventricular catheter was confirmed before each study by checking the pressure waveforms.

At the end of the experiment the ewes were killed with an overdose of pentobarbital sodium (600 mg), and tissues of interest were dissected, weighed, homogenized, and placed in preweighed counting vials. The uterus (myometrium and endometrium), fetal membranes, and fetal organs were treated in a similar manner. The cotyledons were counted individually to confirm uniform distribution of microspheres to the cotyledons and the results were totaled.

Reference blood and tissue sample vials were counted in conjunction with standard and background vials in an automated gamma counter, and nuclide separation was performed by computer. Flow was calculated as: (Number of microspheres per gram times reference sample flow rate) divided by Number of microspheres in reference sample. Umbilical flow in the two groups was also normalized by expression as a ratio to the total splanchnic flow. Splanchnic flow was calculated as the total of liver, spleen, pancreas, kidney, stomach, and intestine flows. Because the reference sample for microsphere determination of blood flow was taken from the lower aorta, flow to these organs was accurately measured.

Total absolute resistance in the umbilical bed was calculated as the quotient of mean arterial pressure minus central (inferior vena cava) venous pressure and total flow. Resistance was also calculated per kilogram cotyledonary mass.

Umbilical artery flow velocity waveform recording. A 4 MHz continuous wave Doppler transducer and directional Doppler blood velocimeter was used (Model D10, Medasonics, Mountain View, Calif.). With the ewe standing, contact jelly was spread over the lower abdomen and the transducer searched until the characteristic fetal umbilical artery waveform sound was heard. Fetal and maternal signals were distinguished by checking the heart rate. The umbilical artery signal could be displayed along with the umbilical vein signal with flow in the opposite direction. It could be distinguished audibly and visually from signals of the fetal aorta. This feature was used in recognition. Unlike flow in intra-abdominal great veins, flow in the umbilical vein does not show cardiac pulsations. Umbilical artery waveforms were recorded from at least four sites for each study. The data were recorded and stored on audiotape to permit later measurement after spectrum analysis (Medasonics SP25) display. Recordings of selected study periods were transferred to ultraviolet paper (Model FOR 1002 fiberoptic recorder, Medelec, Woking, England) or Polaroid film for measurement. The peak systolic and least diastolic flow velocities were measured and their ratio calculated by averaging the ratio from each site during the study period.

Miscellaneous. Arterial venous and amniotic pressures

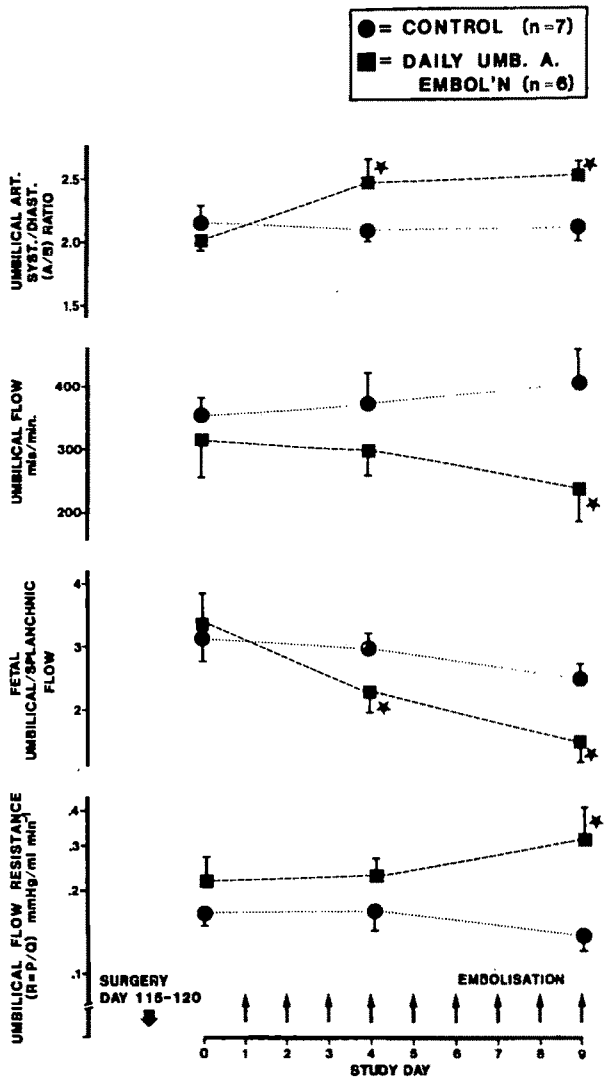

Fig. 1. Mean (±SEM) results of the fetal studies in the control group and in those in whom the umbilical arteries were embolized daily. Significant differences ($p < 0.05$) between the control and embolized groups are shown (*).

were recorded by a pressure transducer (Bell and Howell, Pasadena, Calif.) and a recorder (Model M19, Devices, Cambridge, England). Maternal and fetal heart rates were determined from the arterial pressure waves. Blood gases and pH were measured by a blood gas analyzer (Radiometer, Copenhagen, Denmark).

Experimental protocol. The study began 4 to 7 days after surgery, with seven control and six animals to be embolized. Blood flow with radioactive microspheres was measured at the start of the study and repeated on days 4 and 9 of the experimental period. Blood samples were taken from the ewe and fetus for blood gas analysis just before these measurements. Umbilical artery flow velocity waveforms were recorded daily.

In the umbilical artery embolization group, approx-

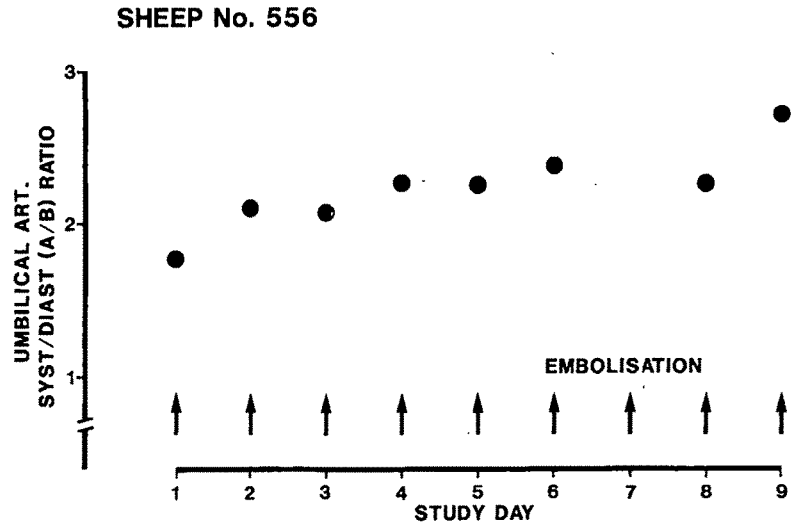

Fig. 2. The umbilical artery systolic/diastolic ratio in one fetal lamb in whom the umbilical circulation was embolized daily.

imately 1.5 million, 15 μm microspheres labeled with cerium 141 were injected each day into the lower abdominal aorta. The use of labeled spheres made it possible to count the number of spheres that traveled via the umbilical arteries to the cotyledons and to check the number of spheres that lodged in the abdominal viscera or lower limbs.

Statistical analysis. Results were analyzed by one-way analysis of variance. Dunnett's test was used for comparison of means between the control and embolized groups and also within the embolized group.[12] A logarithmic transformation was used for the calculated resistance, as this is the ratio of two normally distributed variables and was not normally distributed.

Results

Repetitive embolization of the umbilical placental circulation was associated with an increase in the peak systolic to least diastolic (A/B) ratio of the umbilical artery flow velocity waveform (Table I; Fig. 1). A representative change in this ratio over time in one of the fetuses embolized is shown in Fig. 2. In the control group over the short study period (9 days), there was no significant change in measures of umbilical flow and resistance and the uterine flow (Table I). The control group values did not differ from the baseline (day 0) values in the embolization group. The total umbilical flow was decreased in the embolized group after 9 days ($p < 0.05$) when expressed in absolute terms and relative to fetal weight. When expressed as a multiple of splanchnic flow, this decrease was significant at both 4 and 9 days ($p < 0.05$; Fig. 1). Splanchnic flows did not differ between the groups. Umbilical placental resistance in the embolized group increased and was significant at 9 days ($p < 0.05$). Resistance per unit tissue (cotyledon) mass was also increased at 9 days. Arterial pressure did not vary between the control and embolized groups. Heart rate showed no difference between control and embolized fetuses during the study. On the maternal side of the placenta, total uterine flow and its uteroplacental component were measured (Table I). There was a nonsignificant trend for these to increase in the control and decrease in the embolized group.

Embolization of the umbilical circulation resulted in a fall in oxygen tension in the fetal blood (Table I). Oxygen tension was significantly lower ($p < 0.05$) at both 4 and 9 days. Carbon dioxide tension, pH, and base excess did not differ within or between the two groups.

Of the total dose of embolizing microspheres injected into the lower aorta of the fetus, a mean of 70% was recovered in the cotyledons (range 56% to 78%). There was <3% in the fetal kidneys and <2% in the gut. No cerium 141 microspheres were recovered from the fetal lungs, heart, or brain, indicating that none passed through the placenta. The number of embolizing microspheres in the kidneys was five times the number from a flow measurement. The content of cerium 141 microspheres in the hind limb skin and muscle biopsy specimens was consistent with the approximately 25% lodgement in hind limb. The number of cerium 141 embolizing microspheres in the cotyledons was 16 to 55 (mean 36) times greater than the number of microspheres injected in the course of the three fetal blood flow measurements. The mean fetal weight of the control (3.44 kg) and embolization (3.74 kg) groups

did not differ significantly, and the fetal/cotyledon weight ratio was similar in the two groups.

Comment

Embolization of the umbilical circulation was carried out to obliterate the peripheral arterial tree in the fetal cotyledons and to observe the effect on umbilical placental flow velocity waveforms. These have been proposed as a simple and sensitive index of umbilical circulation and related to fetal welfare.[1-4,5] Umbilical placental resistance was increased by embolization. Embolization resulted in a change in the pattern of the umbilical flow velocity waveform, with an increase in the systolic/diastolic ratio. There was a reduction in the volume flow in the umbilical circulation relative to the control group in both absolute terms and when expressed as a multiple of the splanchnic circulation. There was no change in arterial pressure. This may have occurred had we continued further embolization. The data on visceral blood flow does not suggest a shutdown of vascular beds to improve umbilical flow.

The change in flow velocity waveform observed after embolization corresponds to the change theoretically predicted as a result of increased peripheral or downstream resistance. With each cardiac impulse, pressure and flow waves travel out along the arterial tree. Wave reflection occurs downstream at the site of arterial branches and especially at the level of the "resistance" vessels.[14] The extent of reflection (reflection coefficient) is increased by narrowing of these channels[13] (reduced cross-section area of resistance vessels of the vascular bed). The waveform observed is the sum of the incident and reflected (negative) waves so that a reduced diastolic component would be predicted if reflection is increased. The systolic/diastolic (A/B) ratio was suggested to quantitate this effect. Other indices used for this purpose include the pulsatility index and the resistance index. We have compared these and shown them to be very highly correlated in the umbilical circulation.[14]

The change in the systolic/diastolic ratio was significant at 4 days, but umbilical resistance was not significantly different until 9 days. These results illustrate the difference between calculated resistance (mean pressure difference/mean flow) for steady flow and the flow velocity waveform resistance indices. The latter are more directly determined by the extent of wave reflection at the periphery of the arterial tree rather than resistance. Embolization could be expected to decrease the cross-sectional area of the umbilical placental vascular bed and so increase reflection. Resistance may be defined as the energy lost in forcing blood through the arterial tree.[15] This energy loss includes components due to the pulsatile nature of blood flow (this can be assessed by measuring impedance), the dimensions of the arterial tree and the viscoelastic properties of its walls (distensibility), physical properties of the blood, and the reflected waves. The change in systolic/diastolic ratio preceding the change in calculated vascular resistance can be explained if there is an alteration in any of the other factors affecting resistance opposite to the waveform reflection effect. It is also possible that some of the effect of microsphere embolization may have been hidden by the continued growth and expansion of the umbilical placental bed with gestational age. This was the explanation suggested when the same observations were made about the maternal uterine blood flow after embolization of the maternal uteroplacental bed.[8] Against this explanation is the rise in the flow velocity waveform systolic/diastolic (A/B) ratio we found after embolization. It is also possible that the fetal cotyledon circulation has a greater potential for opening collateral channels than observed in some other tissues in response to microsphere embolization. However, this explanation is not likely because there was a downward alteration in flow in the embolized group.

There was a change in umbilical flow at 9 days that was not significant at 4 days, although the umbilical/splanchnic flow ratio was decreased. Evidence of the preservation of umbilical flow despite an increase in systolic/diastolic ratio in human pregnancy exists.[16] Volume flow in the thoracic aorta and umbilical vein was compared in human fetuses with subsequent birthweight appropriate and small-for-gestational age. The umbilical flow was shown to be 40% of aortic flow in appropriate for gestational age fetuses, but 21% in the small for gestational age group. The umbilical volume flow was of the same magnitude in the two groups, yet the systolic/diastolic ratio was increased in the small for gestational age group. Similar findings were reported in growth-retarded fetal lambs.[11] These observations suggest an increase in cardiac output.

The umbilical artery flow velocity waveforms are similar in normal ovine and human pregnancy. In human pregnancy the two umbilical arteries run from the fetus to the placental disc. In ovine pregnancy the umbilical vessels branch to the many cotyledons. For this reason it is necessary to make multiple observations of the umbilical artery at different sites to derive an averaged systolic/diastolic ratio.

We are not aware of any previous reports of embolization of the umbilical circulation. Embolization of the uterine circulation[7-9] has been used to provide a model of fetal growth failure or asphyxia. Ligation of one umbilical artery has also been studied for a similar reason. Because an alteration in umbilical flow velocity waveform as indicated by an increase in the sys-

tolic/diastolic (A/B) ratio is an early feature of fetal growth retardation, with definite placental pathologic correlation[6] and only sometimes a coexistent alteration in the uterine circulation,[5] umbilical artery embolization may provide a better model for the study of intrauterine growth retardation than does uterine embolization. Our study period (9 days) was too short to affect significantly the fetal weight.

Bound volumes available to subscribers

Bound volumes of the American Journal of Obstetrics and Gynecology are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the Journal name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular Journal subscription.

Continuous estrogen/progestin therapy in menopause

Stanley G. Prough, M.D., Sezer Aksel, M.D., R. Herbert Wiebe, M.D., and Janet Shepherd, M.D.
Mobile, Alabama

The incidence of vaginal bleeding, endometrial histology, menopausal symptoms, blood pressure, and serum lipid concentrations were evaluated in 26 women who received either continuous conjugated equine estrogens and medroxyprogesterone acetate (group I, N = 16) or cyclic conjugated equine estrogen + medroxyprogesterone acetate (group II, N = 10) over a 9-month treatment period. At the end of therapy, endometrial biopsy specimens in group I revealed inactive endometrium, whereas one of ten biopsy specimens in group II showed proliferative endometrium. Blood pressure, serum total cholesterol, high-density and low-density lipoprotein cholesterol, and triglyceride levels were not significantly altered from baseline in either group during the 9-month treatment. Vaginal bleeding was virtually eliminated in group I by the end of the study, while 80% of the patients in group II continued to have cyclic menses ($p < 0.001$). This pilot study suggests that continuous conjugated equine estrogen plus medroxyprogesterone acetate therapy appears to be a satisfactory method of postmenopausal hormone replacement, effectively reducing menopausal symptoms without any apparent short-term alterations in serum lipids. It has the added benefit of eliminating cyclic menstrual flow. (Am J Obstet Gynecol 1987;157:1449-53.)

Key words: Menopause, estrogen replacement therapy, progestin therapy

Estrogen replacement is an important part of the preventative health care of postmenopausal women. The utilization of estrogens for the relief of menopausal complaints, such as atrophic vaginitis and vasomotor symptoms,[1] and the prevention of osteoporosis[2] is well established. In addition, the postmenopausal use of estrogens may also reduce the incidence and risk of coronary artery disease.[3, 4] Despite these benefits, many women are reluctant to use cyclic estrogen/progestin replacement therapy because of the problems of vaginal bleeding and recurrence of vasomotor symptoms during the week off of therapy. Some women may choose not to use postmenopausal hormone therapy because of the perceived risk of endometrial cancer, even though the addition of a progestin to conjugated equine estrogen will reduce the risk of endometrial neoplasia.[5, 6] Furthermore, progestin-related side effects such as breast tenderness, headache, nausea, abdominal bloating, and depression, are additional reasons for patient dissatisfaction with cyclic therapy. Therefore, we compared continuous estrogen/progestin therapy to cyclic estrogen/progestin therapy, assessing the relief of vasomotor symptoms and the effect of therapy on blood pressure, endometrial histology, lipid profiles, and the occurrence of uterine bleeding.

Methods

Menopausal patients with intact pelvic organs who sought estrogen replacement therapy for the relief of menopausal symptoms from the Reproductive Endocrine Division, Department of Obstetrics and Gynecology at the University of South Alabama, were placed in two randomized parallel study groups. Group I consisted of 16 women 42 to 66 years of age, and group II consisted of 10 women 44 to 66 years of age. All patients had been amenorrheic for at least 1 year and had follicle-stimulating hormone (FSH) levels in the menopausal range at the onset of the study. Any patient who was receiving hormone replacement before the start of the study had been amenorrheic for at least 1 year. An elevated FSH level as a baseline, off of estrogen therapy, was a prerequisite to participation in the treatment plan. All patients receiving hormone replacement at the onset of the study had a 6-week washout period before inclusion in either study group. Patients with unexplained vaginal bleeding, liver disease, ischemic heart disease, hyperlipidemia, diabetes, acute or recent vascular thrombosis, or carcinoma of the breast or endometrium were excluded from the study. Informed consent regarding estrogen/progestin replacement therapy and the patient's inclusion in the study protocol was obtained from each patient at the onset of participation in the study. The protocol was approved by the Committee for the Protection of Human Subjects at the University of South Alabama.

The study encompassed a 9-month treatment period in which group I was given 0.625 mg conjugated

Table I. Survey of symptoms

equine estrogen (Premarin; Ayerst Laboratories, Inc., New York, New York) and 2.5 mg medroxyprogesterone acetate (Provera; Upjohn Manufacturing Company, Kalamazoo, Michigan) daily. Group II received 0.625 mg conjugated equine estrogen daily during days 1 through 25 of each cycle and medroxyprogesterone acetate 10 mg daily during days 16 to 25.

A baseline endometrial biopsy specimen, fasting lipid profile, weight, blood pressure, and a 13-symptom diary (Table I) were obtained from each patient before the start of therapy. All of these factors were reassessed after 3 and 9 months of therapy in group I and at 9 months in group II. Endometrial biopsy specimens were obtained by Novak curette or endometrial pipelle (Unimar, Inc., Willmington, Connecticut) from the uterine fundus. In group II, biopsies were performed during the progestin phase of the cycle. The biopsy specimens were reviewed by a pathologist and one of the physician members of the Division of Reproductive Endocrinology, with concurrence by all interpreters. Fasting lipid profiles obtained at 8:00 AM included cholesterol, high-density lipoprotein (HDL) cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels. Samples from group II were obtained during the later portion of progestin therapy. Repeat lipid profiles were measured after 3 months of therapy in group I, to ascertain if demonstrable adverse effects of combined estrogen-progestin therapy on lipids would warrant discontinuation of treatment. Lipid profiles were obtained at 9 months of therapy in both groups.

The total cholesterol level was measured by the enzymatic method of Cholesterol Rate Dristat No. 6804006 (Beckman Instruments, Somerset, N.J.), and the triglyceride level was measured by the Triglyceride UV Rate Dristat No. 68323 (Beckman Instruments). Both were analyzed by an RA 1000 Discrete Analyzer (Technicon, Raritan, N.J.). HDL cholesterol was measured by a rapid precipitation technique with equal volumes of 2 mol/L $MgCl_2$ and dextran sulfate (molecular weight 500,000; 2 gm/dl) with 0.1 ml of precipitating agent added to 1.0 ml of serum. The solution was mixed, incubated at room temperature for 10 minutes, centrifuged for 20 minutes, and the supernatant assayed for HDL cholesterol. LDL cholesterol was calculated by the Friedwald equation: LDL = Total cholesterol − HDL cholesterol − (triglyceride divided by 5).[7] An approximation of cardiac risk was assessed by the LDL/HDL ratio.[8] The 13-symptom diary maintained by the patient was assessed and compiled by the investigators.

Data were analyzed by the SAS-5 computer program (SAS Instruments, Inc., Cary, North Carolina) and statistical analysis was performed by analysis of variance, the Duncan-Tukey multiple range tests for variables, Fisher's exact test, and paired t test, with significance regarded as a p value < 0.05. All values reported are the mean ± SEM.

Results

As shown in Table II, age, height, weight, and ponderal index were comparable in both groups. Throughout the treatment period, blood pressure was not significantly altered by either method of hormone replacement (Table III).

Improvement in menopausal symptoms was noted in both groups. The occurrence of hot flashes, atrophic vaginitis, and mastodynia was comparable in both groups in regard to incidence and severity. The duration of vaginal bleeding was greater in group II than in group I. The incidence of symptoms (expressed as percent patients with complaints) is shown in Fig. 1.

Vaginal bleeding was virtually eliminated in group I. After 9 months of therapy, 2 patients experienced one episode of spotting. By contrast, eight of 10 patients in group II continued to have cyclic bleeding during the week of no therapy. The difference between group I and group II regarding vaginal bleeding was significant ($p < 0.001$, Fisher's exact test; Fig. 1).

In group I, at the start of therapy, endometrial biopsy revealed proliferative endometrium in five subjects and inactive endometrium in 11. After 9 months of therapy, inactive endometrium was noted in all subjects.

In group II, before the start of therapy, endometrial biopsy revealed inactive endometrium in eight patients, proliferative endometrium in one, and mild hyperplasia in one. The mild hyperplasia was confirmed by diagnostic dilation and curettage. After 9 months of cyclic

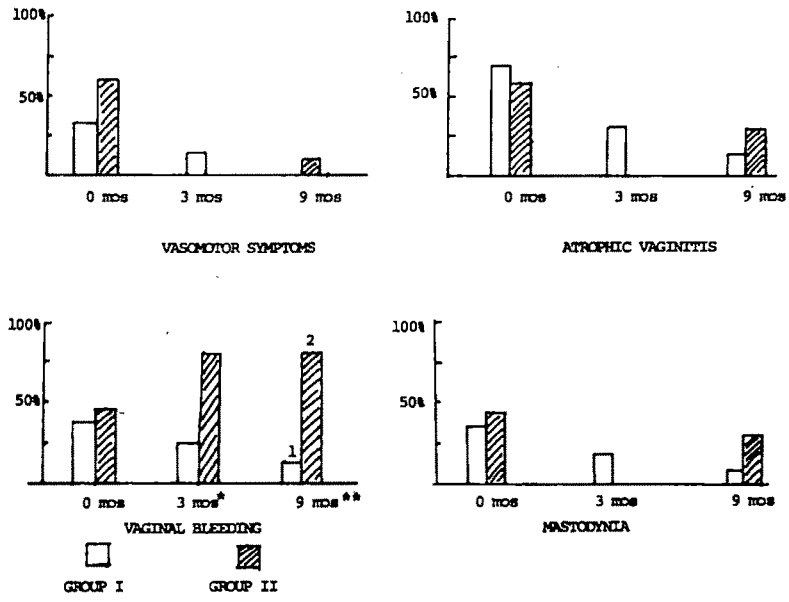

Fig. 1. Percentage of patients with any occurrence of the four listed symptoms without regard to severity. *Open bars* represent group I; *hatched bars* represent group II. Cardiac risk is defined as the LDL/HDL ratio, with an average risk for women of 3.22.[8] *1*, Spotting (one episode); *2*, cyclic bleeding; *p < 0.01; **p < 0.001.

Table II. Mean age, height, weight, and ponderal index at onset of therapy in groups I and II

	Age (yr)	*Height (m)*	*Weight (kg)*	*Ponderal index*

Data are $\bar{x}$ ± SEM.

conjugated equine estrogen + medroxyprogesterone acetate therapy, endometrial biopsy revealed inactive endometrium in nine subjects, while the remaining subject showed a conversion from inactive to proliferative endometrium.

As shown in Table IV, total cholesterol did not change significantly during the course of therapy in either group. In group I, the mean HDL cholesterol concentration at 3 months was comparable to baseline. However, a trend toward an increase in HDL cholesterol levels was noted at 9 months. In group II, a trend toward an increase in HDL cholesterol and a decrease in LDL cholesterol was noted over the 9-month treatment. These changes were not statistically significant.

Comment

We have demonstrated that continuous estrogen/progestin therapy and cyclic estrogen/progestin therapy were equally effective in relieving symptoms of atrophic vaginitis and hot flashes. The use of estrogen replacement therapy did not cause any significant side effects, including a change in blood pressure. This is in agreement with results obtained by other investigators.[9, 10]

It has been suggested that one of the major benefits of estrogen replacement therapy may be the cardioprotective effect of estrogen-induced changes in serum lipids.[11, 12] The increase in HDL cholesterol is thought

to be the most cardioprotective factor.[13, 14] However, various progestational agents used to counteract the estrogen effect on the endometrium have been reported to reverse this beneficial effect of estrogen.[15, 16]

Although a trend toward increased HDL cholesterol was noted in women receiving estrogen therapy, we were not able to show a definite beneficial effect of estrogen on serum lipids in either group. A temporary beneficial effect on serum lipid concentrations during the estrogen phase of therapy that was reversed during progestin administration is possible. As demonstrated by others,[16, 17] our study with low-dose medroxyprogesterone acetate showed no statistically significant change in HDL cholesterol concentrations over the 9-month treatment. This is comparable to Weinstein's recent data.[18] Whether the reversal of the estrogen-induced changes in lipids by medroxyprogesterone acetate will abrogate the apparent cardioprotective benefit of estrogen therapy is unknown. The trend toward an increase in HDL cholesterol levels in both groups requires additional evaluation and would be best delineated with an extended period of study of larger groups. Our preliminary study would indicate that lipid parameters, HDL cholesterol in particular, are comparable in women receiving cyclic or combined continuous therapy and in women without estrogen/progestin replacement.

Although our short-term combined estrogen/progestin study cannot address the issue of osteoporosis, medroxyprogesterone acetate as well as conjugated equine estrogen have been associated with improvement in the retardation of bone loss. It has been suggested that estrogen and progestin may act synergistically to improve bone metabolism.[19]

Vaginal bleeding was virtually eliminated in the group receiving continuous estrogen/progestin therapy in our study, while cyclic vaginal bleeding was common in the traditional cyclic therapy groups. Our findings are in contrast with those of Clisham et al.,[20] who continuously administered 0.625 or 1.25 mg conjugated equine estrogen and 10 mg medroxyprogesterone acetate but were unable to avoid vaginal bleeding in their patients. The high incidence of vaginal bleeding they noted may have been due to progestational atrophy, as bleeding decreased after the dose of conjugated equine estrogen was increased to 1.25 mg daily. In our study, the incidence of vaginal bleeding at 3 months of therapy in the continuous regimen was significantly less than in the cyclic group ($p < 0.01$, Fisher's exact test), and was less common than that reported by Weinstein[18] (25% versus 50%), who used a dosage schedule comparable to ours for only 3 months. With continued treatment past 3 months, the incidence of vaginal bleeding in our study was almost eliminated.

By the use of low-dose (2.5 mg) medroxyprogesterone acetate daily in our treatment program, we were able to prevent the development of endometrial hyperplasia and avoid vaginal bleeding. The apparent protective effect of low-dose progestin treatment on the endometrium and the absence of vaginal bleeding has been previously reported with the use of norethindrone.[21]

The use of continuous conjugated equine estrogen + medroxyprogesterone acetate therapy for the treatment of menopausal symptoms should gain acceptance by most menopausal women. It effectively controls the symptoms of menopause with the added benefit of eliminating vaginal bleeding. The apparent lack of side effects, the protective effect on the endometrium, and the potential benefit of preventing osteoporosis makes this treatment regimen attractive. Although a beneficial effect on serum lipids could not be demonstrated with this therapy, lipid parameters were not different when no treatment was used. Longer and extended longitudinal studies are required not only to assess potential serum lipid alterations, but also to ascertain the long-term beneficial or adverse effects of this mode of therapy.

Arachidonate lipoxygenase metabolites in amniotic fluid of women with intra-amniotic infection and preterm labor

Roberto Romero, M.D.,* Ruben Quintero, M.D., Mohamed Emamian, M.D., Macor Wan, M.D., Camille Grzyboski, C.L.T., John C. Hobbins, M.D., and Murray D. Mitchell, D.Phil.

New Haven, Connecticut, and San Diego, California

This study was undertaken to examine the effects of intrauterine infection and preterm labor on the amniotic fluid concentrations of arachidonate lipoxygenase metabolites in women with premature rupture of membranes. Amniotic fluid was obtained from four groups of women with premature rupture of membranes: group 1, women without labor or infection; group 2, women with labor but without infection; group 3, women with intra-amniotic infection but without labor; and group 4, women with both infection and labor. 12-Hydroxyeicosatetraenoic acid, 15-hydroxyeicosatetraenoic acid, and leukotriene B_4 were measured by radioimmunoassays. Amniotic fluid concentrations of 12-hydroxyeicosatetraenoic acid were found not to differ significantly among the four groups. Amniotic fluid concentrations of 15-hydroxyeicosatetraenoic acid in group 4 were significantly higher than in women in groups 1 and 3 ($p < 0.05$). In addition, amniotic fluid concentrations in leukotriene B_4 were significantly higher in group 4 than in any of the other three groups ($p < 0.05$). Leukotriene B_4 concentrations were higher in groups 2 and 3 than in group 1, suggesting that the presence of both labor and infection increases the concentration of this metabolite in amniotic fluid. Infection and labor had an additive effect in the elevation of amniotic fluid concentrations of leukotriene B_4. These results suggest that the amniotic fluid concentrations of arachidonate lipoxygenase metabolites are affected differently by the presence of infection and labor in women with premature rupture of membranes. (AM J OBSTET GYNECOL 1987;157:1454-60.)

Key words: Arachidonate lipoxygenase, intra-amniotic infection, premature rupture of membranes

Intra-amniotic infection is frequently associated with the onset of labor.[1] The mechanisms responsible for parturition in these cases have not been established. Parturition at term is associated with mobilization of arachidonic acid from fetal membranes.[2] Arachidonic acid can be metabolized either by way of the cyclooxygenase or lipoxygenase pathways. The former pathway leads to the synthesis of prostaglandins and thromboxanes, whereas the latter pathway leads to the formation of lipoxygenase products such as hydroxyeicosatetraenoic acids and leukotrienes. Arachidonate lipoxygenase products are generated during the course of inflammatory reactions[3] and can be synthesized by human intrauterine tissues.[4] These products have been found to be involved in the development of uterine contractions,[5,6] and they may participate in the normal process of labor or in the mechanism of labor that is associated with or the result of an inflammatory reaction (e.g., chorioamnionitis). The purpose of this study was to determine the concentrations of arachidonate lipoxygenase metabolites in amniotic fluid of women with and without intra-amniotic infections and to evaluate the relative influence of labor and infection on the amniotic fluid levels of these compounds.

Material and methods

Study design. A cross-sectional study was constructed according to the results of amniotic fluid cultures in women with premature rupture of membranes. Four groups were created: group 1, women without labor or infection; group 2, women with labor but without infection; group 3, women with an intra-amniotic infection but without labor; and group 4, women with both infection and labor. An intra-amniotic infection was defined as the presence of a positive amniotic fluid culture. None of the patients in this study developed

signs and symptoms of infection. Labor was defined as the presence of regular uterine contractions that led to cervical dilatation and spontaneous vaginal delivery within 24 hours of the performance of the amniocentesis. Pelvic examination was not performed at the time of amniocentesis, since this could result in a higher incidence of infection.[7] Women were classified according to the results of amniotic fluid culture and their labor status at the time of amniocentesis.

Retrieval of amniotic fluid. Amniotic fluid was obtained by transabdominal amniocentesis in women admitted to Yale–New Haven Hospital with the diagnosis of rupture of membranes at a gestational age of less than 37 weeks. Our success rate in obtaining fluid from these women is 95%. Amniotic fluid was processed for Gram stain, culture, lecithin/sphingomyelin ratio, and phosphatidylglycerol, and any remaining fluid was stored at −20° C. Immediately before amniocentesis, the presence or absence of uterine contractions was recorded by external tocodynamometry.

Culture technique. Amniotic fluid obtained by transabdominal amniocentesis was transported to the laboratory in a capped, plastic syringe immediately after collection of the specimen. These conditions precluded air contact with the specimen. Plating occurred within 30 minutes of collection in all cases. The samples were plated on blood agar, MacConkey agar, Columbia colistin–nalidixic acid agar, chocolate agar (36° C in 8% carbon dioxide) for aerobic culture and blood agar, bacteroides and bile-esculin agar/laked kanamycin and vancomycin agar, and Martin-Lewis agar (all prereduced) for anaerobic culture. Amniotic fluid was also inoculated in thioglycolate broth. Anaerobic cultures were grown in an anaerobic chamber in a Forma Scientific anaerobic system (Model 1024, Division of Mallinckrodt, Marietta, Ohio). The number of colony-forming units per milliliter was determined by plating the specimen with a 0.01 and 0.001 calibrated urine loop. Each colonial morphotype was identified to species by Food and Drug Administration-Centers for Disease Control–approved commercial systems supplemented by conventional tests when needed. An identification was accepted only when it yielded a normalized probability of 97% or greater. When more than three organisms were grown from an amniotic fluid sample, the infection was referred to as "mixed aerobic or anaerobic flora." Species identification was not conducted in these cases. This protocol evolved, since it was frequently difficult to identify all bacterial species involved, and there was no evidence that this effort altered patient management. There was also no evidence that amniotic fluid concentrations of lipoxygenase products would be preferentially affected by some organisms. Identification of anaerobes was conducted with the IDS RapID ANA system (Innovative Diagnostic System, Atlanta, Ga.). Agar was obtained from Baltimore Biological Laboratories, Cockeysville, Md.

***Mycoplasma* and *Ureaplasma* cultures.** Amniotic fluid was centrifuged at 2000 g for 20 minutes and the sediment was placed into 2 ml of holding media (pleuropneumonia-like organism broth, which was supplemented with fresh yeast extract and horse serum, penicillin, polymyxin B, and amphotericin). Samples were stored at −70° C until culture (Mycotrim-GU, Berkeley, Calif.).

Lipoxygenase metabolite determinations. Arachidonate lipoxygenase products were extracted from amniotic fluid into acidified diethyl ether (five volumes). The solvent was evaporated under nitrogen, and the residue was dissolved in assay buffer and assayed using specific radioimmunoassays for 15-hydroxyeicosatetraenoic acid, 12-hydroxyeicosatetraenoic acid, and leukotriene B_4 (Seragen, Inc., Boston, Mass.). Extraction efficiency was determined by assessment of the recovery of each radiolabeled lipoxygenase product added to an aliquot of an amniotic fluid pool. The extraction efficiency was 76% for leukotriene B_4, 91% for 12-hydroxyeicosatetraenoic acid, and 87% for 15-hydroxyeicosatetraenoic acid. All measurements of amniotic fluid samples were conducted in the same assay. One hundred microliters of amniotic fluid was used in the radioimmunoassay. Intra-assay coefficients of variation were 12% for leukotriene B_4, 11% for 15-hydroxyeicosatetraenoic acid, and 10% for 12-hydroxyeicosatetraenoic acid. Sensitivities of the assays for 12-hydroxyeicosatetraenoic acid and 15-hydroxyeicosatetraenoic acid were 8 pg, whereas it was 4 pg for leukotriene B_4. Inhibition of the binding of the radioligand to the antibody by 50% was achieved by 90 pg for leukotriene B_4, 170 pg for 15-hydroxyeicosatetraenoic acid, and 260 pg for 12-hydroxyeicosatetraenoic acid. Serial sample dilutions were parallel to the standard curve for each assay (slope comparisons: $p > 0.05$). Solvent blanks for leukotriene B_4, 15-hydroxyeicosatetraenoic acid, and 12-hydroxyeicosatetraenoic acid were 8 pg, 29 pg, and 98 pg, respectively. Solvent blanks were subtracted from measured values.

Statistical analysis. The Kolmogorov-Smirnov test was used to test the hypothesis that lipoxygenase products were normally distributed. Logarithmic transformation was required for normality in 15-hydroxyeicosatetraenoic acid. The amniotic fluid concentrations of 12-hydroxyeicosatetraenoic acid were normally distributed, but those of leukotriene B_4 were not. One-way analysis of variance was used to compare the levels of lipoxygenase metabolites in the four different groups for 12-hydroxyeicosatetraenoic acid and log 15-hydroxyeicosatetraenoic acid. Duncan's multiple

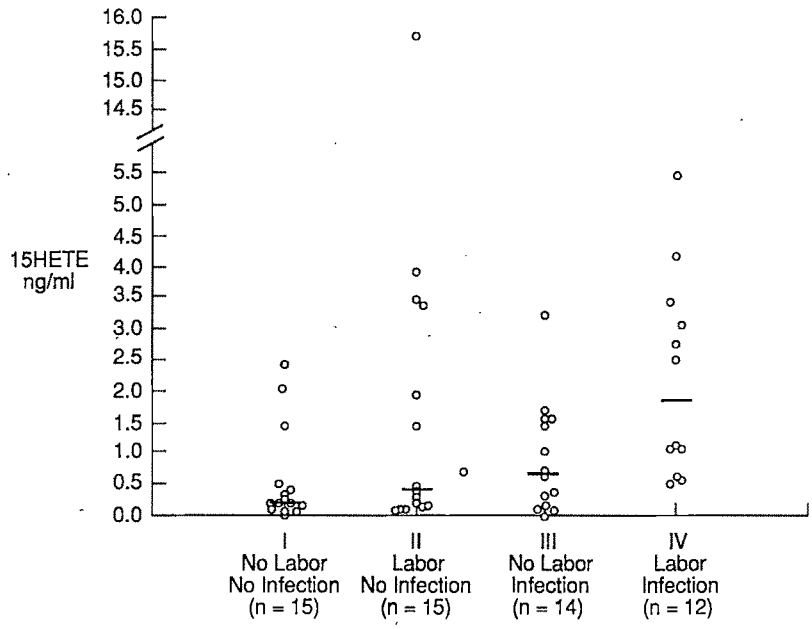

Fig. 1. Amniotic fluid concentrations of 15-hydroxyeicosatetraenoic acid (15-HETE) in the following four groups of women: group 1, women without labor or infection; group 2, women with labor but without infection; group 3, women with an intra-amniotic infection but without labor; and group 4, women with both infection and labor. Logarithmic transformation was required for normality to be achieved. One-way analysis of variance was used to compare the amniotic fluid concentrations of 15-hydroxyeicosatetraenoic acid among the four different groups ($F = 4.02$; $p < 0.05$). A significant difference was found only between groups 1 and 4 and groups 3 and 4 ($p < 0.05$, Duncan's multiple range test). The median concentration of each group is represented by the line in the scattergram of each group.

range test was used for comparison between the different groups. A p value <0.05 was considered statistically significant. Kruskal-Wallis test was used to compare the amniotic fluid concentrations of leukotriene B_4 among different groups. A logarithmic transformation was not used because many patients had nondetectable levels. Multiple comparisons among the four groups were carried out following the procedure described by Conover.[8]

Results

The concentrations of 15-hydroxyeicosatetraenoic acid, leukotriene B_4, and 12-hydroxyeicosatetraenoic acid in amniotic fluid from women in the four different groups are illustrated in Figs. 1 through 3, respectively. The concentration of 12-hydroxyeicosatetraenoic acid in amniotic fluid did not vary significantly among groups (analysis of variance, $p > 0.05$), whereas differences were detected in the levels of 15-hydroxyeicosatetraenoic acid and leukotriene B_4 (analysis of variance, $p < 0.05$). Amniotic fluid concentrations of 15-hydroxyeicosatetraenoic acid were greater in group 4 than in group 1 ($p < 0.05$, Duncan's multiple range test) and greater in group 4 than in group 3 ($p < 0.05$, Duncan's multiple range test). Amniotic fluid concentrations of leukotriene B_4 were significantly different among all groups except for the comparison between groups 2 and 3. Table I illustrates the descriptive statistics for each group. Tables II and III show the results of quantitative microbiology and amniotic fluid concentrations of lipoxygenase products of women with intra-amniotic infections (groups 3 and 4). No consistent relationship between arachidonic lipoxygenase metabolite concentrations in amniotic fluid and specific organisms isolated from the fluid could be demonstrated. No difference in the time interval between amniocentesis and delivery was found in the groups of women in labor at the time of the amniocentesis (groups 2 and 4) ($p > 0.5$, Wilcoxon rank test).

Comment

The results of this study suggest that the amniotic fluid concentrations of 12-hydroxyeicosatetraenoic acid, 15-hydroxyeicosatetraenoic acid, and leukotriene B_4 are affected differently by infection and labor in women with premature rupture of membranes. No differences were detected in the levels of 12-hydroxyeicosatetraenoic acid in amniotic fluid among the four groups; this was not the case with amniotic fluid concentrations of leukotriene B_4 and 15-hydroxyeicosatetraenoic acid. Therefore it appears that differences exist in the activity of the enzymatic path-

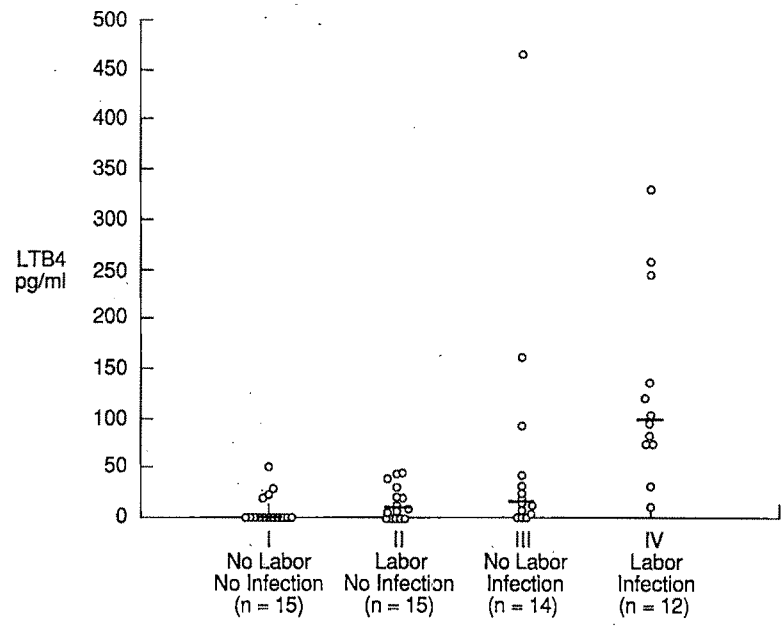

Fig. 2. Amniotic fluid concentrations of leukotriene B_4 (LTB4) in the following four groups of women are displayed: group 1, women without labor or infection; group 2, women with labor but without infection; group 3, women with an intra-amniotic infection but without labor; and group 4, women with both infection and labor. A Kruskal-Wallis analysis of variance was performed to compare amniotic fluid concentrations among the different groups ($p < 0.01$). Amniotic fluid concentrations of leukotriene B_4 were significantly greater in group 4 than in any of the other groups. Amniotic fluid concentrations of leukotriene B_4 were significantly lower in group 1 than in groups 2 and 3. There were no differences between groups 2 and 3 ($p > 0.05$). The median concentration of each group is represented by the line in the scattergram of each group.

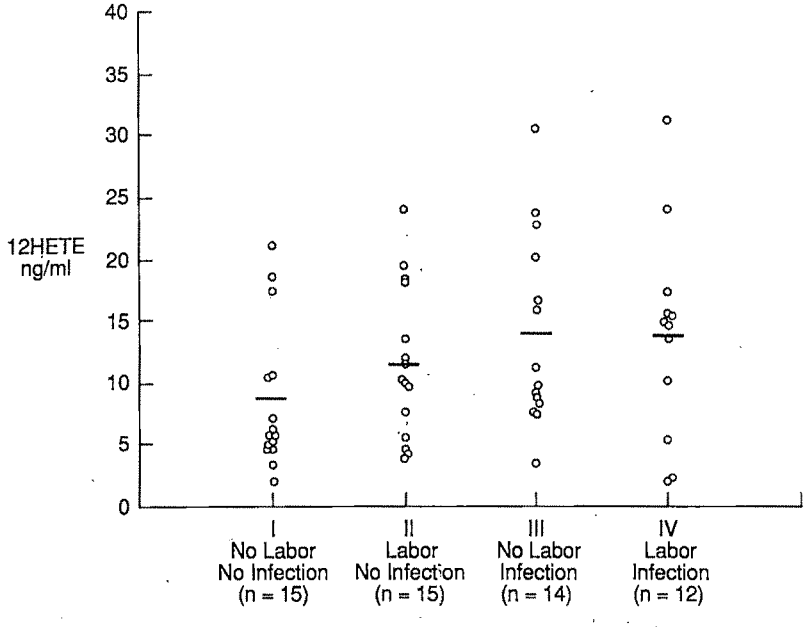

Fig. 3. Amniotic fluid concentrations of 12-hydroxyeicosatetraenoic acid (12-HETE) in the following four groups of women are displayed: group 1, women without labor or infection; group 2, women with labor but without infection; group 3, women with an intra-amniotic infection but without labor; and group 4, women with both infection and labor. One-way analysis of variance was used to compare the amniotic fluid concentrations of 12-hydroxyeicosatetraenoic acid. There were no significant differences in amniotic fluid concentrations of 12-hydroxyeicosatetraenoic acid among the four different groups ($F = 1.80$, $p > 0.05$). The mean concentration of each group is represented by the line in the scattergram of each group.

ways or the degradation of these compounds in intrauterine tissues. Infection and premature labor may not result in activation of the pathway responsible for the biosynthesis of 12-hydroxyeicosatetraenoic acid; however, these clinical conditions may result in effects on the pathways responsible for the biosynthesis or degradation of 15-hydroxyeicosatetraenoic acid and leukotriene B_4. Alternatively, these results may be explained by differences in the concentration of arachidonic acid. Depending on the Michaelis constant of the enzymes of the different lipoxygenase pathways for arachidonic acid and other substrates, the changes observed could be partially caused by alterations in the concentrations of arachidonic acid.

We have found that premature labor alone in women with premature rupture of membranes does not alter the amniotic fluid concentrations of 12-hydroxyeicosatetraenoic acid or 15-hydroxyeicosatetraenoic acid but

only that of leukotriene B_4. This finding is interesting because it appears to be at variance with the results of our earlier study in which women in term labor had significantly elevated concentrations of all these compounds.[9] There are several reasons why such differences may exist. For instance, in our earlier study, all women were in active labor with a cervical dilatation of 6 cm or greater, whereas in the current study, the women are likely to have been in much earlier labor. Data on cervical dilatation are not available because pelvic examinations were not performed in women with premature rupture of membranes, since this procedure may increase the incidence of infection.[7] It can also be argued that a maturational event may account for the differential release of lipoxygenase products into amniotic fluid. Women in preterm labor have lower concentrations of cyclooxygenase metabolites (i.e., prostaglandins) in amniotic fluid and plasma than laboring women at term.[10-12] A similar phenomenon may occur with lipoxygenase metabolites. Evidence supporting this concept is that many women with preterm premature rupture of membranes had nondetectable concentrations of leukotriene B_4 in the present study and that all nonlaboring women at term with intact membranes had detectable concentrations of leukotriene B_4.[9] However, these two groups of women were not identical with respect to membrane status. Intra-amniotic infections alone seemed to affect only the amniotic fluid concentrations of leukotriene B_4 (comparison between groups 1 and 3). It remains to be established whether the increased amniotic fluid concentration of this compound is the result of bacterial or host signals on the metabolism or availability of arachidonic acid.

When both labor and infection are present, the potential relative effects of these two clinical conditions on the amniotic fluid concentration of lipoxygenase metabolites are not easy to interpret. Amniotic fluid concentrations of leukotriene B_4 were significantly elevated in women infected and in labor (group 4) compared with all other groups. This seems to imply that labor and infection have an additive effect on amniotic fluid concentrations of leukotriene B_4. Since amniotic fluid concentrations of prostaglandins are increased with progressive cervical dilatation,[11] it may be hypothesized that the difference observed in amniotic fluid concentrations of leukotriene B_4 between groups 2 and 4 could be attributed to differing cervical dilatation at the time of amniocentesis between the groups. However, this is not likely to be the case because the time interval between amniocentesis and delivery was not different between these two groups.

Significant differences in amniotic fluid concentrations of 15-hydroxyeicosatetraenoic acid were only detected when labor and infection were present (group 4) compared with groups 1 and 3 but not compared with group 2. Further studies will be required to establish the relative contribution of preterm labor and infection to amniotic fluid concentrations of 15-hydroxyeicosatetraenoic acid as this study is not conclusive.

In conclusion, our data indicate that amniotic fluid concentrations of arachidonate lipoxygenase metabolites are affected by the presence of labor and infection in women with preterm premature rupture of membranes. Preterm labor is associated with increased amniotic fluid concentration of leukotriene B_4. Intra-amniotic infection without labor is also associated with increased amniotic fluid concentrations of leukotriene B_4. The presence of preterm labor and intra-

amniotic infection had an additive effect on the increase of amniotic fluid concentrations of leukotriene B_4. Neither preterm labor nor infection was associated with significant changes in amniotic fluid concentrations of 12-hydroxyeicosatetraenoic acid. These observations are consistent with the possibility of an involvement of the lipoxygenase pathway of arachidonic acid metabolism in the mechanism of human parturition associated with preterm labor and intra-amniotic infection.

Correction

In the article by Key, Giuffrida, and Moore, entitled "Predictive value of early pregnancy glycohemoglobin in the insulin-treated diabetic patient" (Am J Obstet Gynecol 1987;156:1096-100), the abstract is incorrect. The correct abstract appears below.

The influence of early pregnancy glycemic control as measured by hemoglobin A_{1c} concentration and the incidence of congenital anomalies and spontaneous abortions were evaluated in women presenting for prenatal care with insulin-treated diabetes in a population whose glycemic control was poor. Thirty-one abnormal outcomes were seen in 83 pregnancies (37%). There were 22 spontaneous abortions and nine major congenital anomalies. No woman with an early pregnancy hemoglobin A_{1c} value <9.5% had an infant with a congenital anomaly and a single woman experienced a spontaneous abortion (4%). Conversely, in women with an early pregnancy hemoglobin A_{1c} value ≥9.5%, congenital anomalies occurred in 24% and spontaneous abortion in 35%. Outcomes of pregnancies in type I and type II diabetic women were comparable. A strong statistical relationship between hemoglobin A_{1c} and adverse pregnancy outcomes was demonstrated. These results strongly suggest that poor glycemic control during early pregnancy adversely influences pregnancy outcomes; the greater the degree of poor control, the greater the impact on pregnancy outcome. The data further justify the need for preconceptional control in diabetic woman and for careful evaluation of the fetus during pregnancy in the woman with insulin-treated diabetes.

Prostaglandin concentrations in amniotic fluid of women with intra-amniotic infection and preterm labor

Roberto Romero, M.D.,* Mohamed Emamian, M.D., Macor Wan, M.D., Ruben Quintero, M.D., John C. Hobbins, M.D., and Murray D. Mitchell, D.Phil.

New Haven, Connecticut, and San Diego, California

This study was undertaken to examine the effects of intrauterine infection and preterm labor on the amniotic fluid concentrations of prostaglandins in women with premature rupture of the membranes. Amniotic fluid was obtained from four groups of patients with premature rupture of the membranes: group 1, patients without labor or infection; group 2, patients with labor but without infection; group 3, patients with an intra-amniotic infection but without labor; group 4, patients with both infection and labor. Prostaglandins E_2 and $F_{2\alpha}$ were measured by radioimmunoassays. Preterm labor, in the absence of infection, was not associated with significant increases in amniotic fluid concentrations of prostaglandins. Women with preterm labor and intra-amniotic infections had higher amniotic fluid concentrations of prostaglandins than women with preterm labor in the absence of infection or women with intra-amniotic infection in the absence of labor. These observations are compatible with the participation of prostaglandins in the mechanisms of onset of preterm labor associated with intra-amniotic infection. (AM J OBSTET GYNECOL 1987;157:1461-7.)

Key words: Prostaglandins, arachidonic acid, premature labor, premature rupture of membranes, intra-amniotic infection, bacteria, labor

Intra-amniotic infection is frequently associated with the onset of labor.[1, 2] The mechanisms responsible for the initiation of parturition under these circumstances have not been established. Several lines of evidence suggest that prostaglandins are involved in the process of normal human parturition.[3-5] It has not been established whether prostaglandins play a role in pathologic human parturition associated with intra-amniotic infection. In a preliminary study we reported that amniotic fluid of women with intra-amniotic infection had higher concentrations of prostaglandins than that of women without infection.[6] However, intra-amniotic infections are frequently associated with the onset of labor. It remains to be established whether this elevation of prostaglandins is secondary to labor, infection, or both. The studies reported in this communication were designed to examine the relationship between intra-amniotic infection and preterm labor and amniotic fluid concentrations of prostaglandins in women with preterm premature rupture of the membranes (PROM).

Material and methods

Study design. A cross-sectional study was constructed according to the results of amniotic fluid cultures in women with PROM. Four groups were created: group 1, women without labor or infection; group 2, women with labor but without infection; group 3, women with an intra-amniotic infection but without labor; group 4, women with both infection and labor. An intra-amniotic infection was defined as the presence of a positive amniotic fluid culture whether or not clinical signs of chorioamnionitis were present. Labor was defined as the presence of regular uterine contractions that led to cervical dilatation and spontaneous vaginal delivery within 24 hours of the performance of the amniocentesis. Pelvic examination was not performed at the time of amniocentesis as this could result in a higher incidence of infection.[7] Patients were classified according to the results of amniotic fluid culture and their labor status at the time of amniocentesis. None of the enrolled patients had clinical signs and symptoms of chorioamnionitis.

Retrieval of amniotic fluid. Amniotic fluid was obtained by transabdominal amniocentesis in women admitted to Yale–New Haven Hospital with the diagnosis of PROM at a gestational age of <37 weeks. In our

institution, the success rate in obtaining fluid from these patients is 95%. Amniotic fluid was processed for Gram stain, culture, lecithin/sphingomyelin ratio, and phosphatidylglycerol. Any remaining fluid was stored at −20° C for research purposes. At the time of amniocentesis the presence or absence of uterine contractions was noted.

Culture technique. Amniotic fluid obtained by transabdominal amniocentesis was transported to the laboratory in a capped plastic syringe immediately after collection of the specimen. These conditions precluded air contact with the specimen. Plating occurred within 30 minutes of collection in all cases. The samples were plated on blood agar, MacConkey's agar, Columbia colistin–nalidixic acid agar, chocolate agar (36° C in 8% carbon dioxide) for aerobic culture and blood agar, BBE (*Bacteroides*, bile-esculin agar)/LKV (laked kanamycin, vancomycin agar), and Martin-Lewis agar (all prereduced) for anaerobic culture. Amniotic fluid was also inoculated in thioglycollate broth. Anaerobic cultures were grown in an anaerobic chamber in a Forma Scientific anaerobic system (Model 1024) (Division of Mallinckrodt, Marietta, Ohio). The number of colony-forming units per milliliter was determined by plating the specimen with a 0.01 and a 0.001 calibrated urine loop. Each colonial morphologic type was identified to species by commercial systems approved by the Food and Drug Administration–Centers for Disease Control and supplemented by conventional tests when needed. An identification was accepted only when it yielded a normalized probability of ≥97%. When more than three organisms were grown from an amniotic fluid specimen, the infection was referred to as being due to "mixed aerobic or anaerobic flora." Species identification was not conducted in these cases. This protocol evolved as it is frequently difficult to identify all bacterial species involved.

***Mycoplasma* and *Ureaplasma* cultures.** Amniotic fluid was centrifuged at 2000 g for 20 minutes and the sediment was placed into 2 ml of holding media (pleuropneumonia-like organism broth, supplemented with fresh yeast extract and horse serum, penicillin, polymyxin B, and amphotericin). Samples were stored at −70° C until inoculation into *Mycoplasma* culturing broth took place (Mycotrim-GU, Berkeley, Calif.).[8]

Prostaglandin determinations. Prostaglandins were extracted from amniotic fluid by use of acidified diethyl ether (five volumes). The organic solvent was evaporated under nitrogen and the residue dissolved in phosphate buffer (pH 7.4). Prostaglandin E_2 and prostaglandin $F_{2\alpha}$ were assayed with sensitive and specific radioimmunoassays according to a technique previously described.[9] The intra-assay coefficients of variation were 7% and 12% and the interassay coefficients of variation were 10% and 15%, respectively. The cross-reactivities of antisera with other major prostaglandins were <1%.

Statistical analysis. A Wilk-Shapiro test was used to test the hypothesis that amniotic fluid prostaglandin concentrations in each group of women were distributed normally. A logarithmic transformation was required for the data to achieve normality. One-way analysis of variance was used to compare the amniotic fluid concentrations of prostaglandins in the four different groups. Duncan's tests were used for comparison between the different groups.

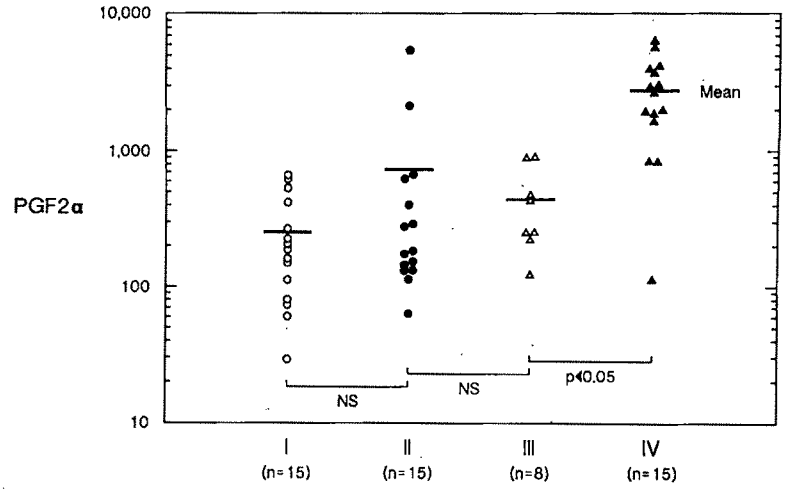

Fig. 1. Amniotic fluid concentrations of prostaglandin $F_{2\alpha}$ in the study groups. Group 1: Women without labor or infection; group 2: women with labor but without infection; group 3: women with intra-amniotic infection but without labor; group 4: women with both infection and labor. Logarithmic transformation was required for normality to be achieved. One-way analysis of variance was used to compare the amniotic fluid concentrations of prostaglandin $F_{2\alpha}$ ($F = 13.13$, $p < 0.001$). Significant differences were found between groups 4 and 3, 4 and 2, and 4 and 1 ($p < 0.05$, Duncan's test).

Group 1: Women without labor or infection; group 2: women with labor but without infection; group 3: women with intra-amniotic infection but without labor; group 4: women with both infection and labor.

Results

Groups 1, 2, and 4 consisted of 15 women each. Group 3 (infection and no labor) was composed of eight women. The maternal age, gestational age at the time of amniocentesis, and parity are depicted in Table I. There were no differences in maternal age among women in all groups. Women in group 4 had a significantly lower gestational age than women in groups 1 and 2 ($p < 0.05$, with analysis of variance and Duncan's test).

The organisms isolated from the amniotic fluid of women with intra-amniotic infections (groups 3 and 4) are depicted in Table II. Mixed aerobic infections and mycoplasma species were the most frequent isolates. There was a single case of *Candida albicans* intra-amniotic infection. The two cases of intra-amniotic infections with coagulase-negative staphylococci occurred in patients who had repeated amniocenteses and pathologic evidence of chorioamnionitis on placental examination.

The amniotic fluid concentrations of prostaglandin $F_{2\alpha}$ in the four different groups of women are shown in Fig. 1. Fig. 2 displays amniotic fluid concentrations of prostaglandin E_2. Descriptive statistics for these data are presented in Tables III and IV. The differences between group 4 and all other groups for both prostaglandins E_2 and $F_{2\alpha}$ were significant ($p < 0.05$ in all instances), while the differences among groups 1, 2, and 3 were not significant ($p > 0.05$).

When amniotic fluid concentrations of prostaglandins of women in labor (groups 2 and 4) and women not in labor (groups 1 and 3) are compared, disregarding the results of bacteriologic examination of am-

niotic fluid, higher concentrations of both prostaglandins could be demonstrated in the laboring group. The amniotic fluid concentrations of prostaglandin E_2 in laboring and nonlaboring women were 1723 ± 370.1 and 570 ± 109.6 pg/ml (mean ± SEM), respectively ($p < 0.05$). The amniotic fluid concentrations of prostaglandin $F_{2\alpha}$ in laboring and nonlaboring women were 1757 ± 344.8 and 318 ± 53 pg/ml, respectively ($p < 0.001$). Similarly, when infected women (groups 3 and 4) are compared with uninfected women (groups 1 and 2), higher amniotic fluid concentrations of prostaglandins are demonstrated in the infected group. The amniotic fluid concentrations of prostaglandin E_2 in infected women and uninfected women were 2238 ± 434 and 444 ± 78 pg/ml (mean ± SEM), respectively (t test, $p < 0.0001$). The amniotic fluid concentrations of prostaglandin $F_{2\alpha}$ in infected and uninfected women were 1968 ± 380 and 491 ± 186 pg/ml, respectively (t test, $p < 0.00001$). Caution is advised in the interpretation of the comparisons between laboring and nonlaboring women and between infected and noninfected women. The design of this study limits extrapolation of these results to a population of women in preterm labor or with intra-amniotic infections without taking into account the interaction of the other variable (labor or infection).

Tables V and VI illustrate the qualitative and quantitative microbiologic features and amniotic fluid-prostaglandin concentrations in infected women of groups 3 and 4, respectively. No appreciable difference was noted in the microbiologic characteristics of the two groups.

Comment

Although increased production of prostaglandins by intrauterine tissues is thought to be a key event in the

initiation of parturition in human labor at term,[3-5] there is conflicting evidence concerning whether prostaglandins have an equally important role in the onset of preterm labor. Concentrations of prostaglandins in amniotic fluid are increased later in women in preterm labor compared with women in labor at term.[10] Moreover, plasma prostaglandin concentrations in women in preterm labor have been shown not to increase to the same extent as in women in term labor.[11] However, one group has recently reported elevated maternal plasma concentrations of the prostaglandin F metabolite in women with preterm labor refractory to tocolytic therapy.[12] As prostaglandins are inflammatory mediators and bacteria involved in intra-amniotic infection are a potential source of phospholipase A_2 activity,[13] it would seem logical to expect that prostaglandins may play a role in the onset of human labor associated with intra-amniotic infections.

We have been unable to document an increase in the amniotic fluid concentrations of prostaglandins between noninfected women with PROM but without preterm labor and noninfected women with PROM but with preterm labor (groups 1 and 2). There are several possible explanations for these findings. First, the women in group 2 (labor without infection) were in very early labor. Amniocentesis was performed in these women for clinical management as this procedure would not be justified ethically in patients in advanced labor or in those in whom delivery was imminent. It is known that concentrations of prostaglandins in amniotic fluid and plasma rise with progressive cervical dilatation, and therefore the magnitude of the difference in amniotic fluid concentration of prostaglandins is partially dependent on the stage of labor in which the sample of amniotic fluid is obtained. It is possible that women in group 2 may not have reached a point in labor at which a significant difference in amniotic fluid prostaglandin concentrations could have been detected. Second, it is possible that the "control" group (group 1, women without infection or labor) had an increased baseline amniotic fluid concentration of prostaglandins associated with the mechanical trauma of rupture of the membranes. This elevation may obscure the detection of differences between groups 1 and 2. Supporting this view is the observation that amniotomy causes a rapid rise in the amniotic fluid and plasma concentrations of prostaglandin.[14, 15] Third, the failure of amniotic fluid prostaglandin concentrations to be elevated in cases of preterm labor unassociated with intra-amniotic infection may reflect an alteration in the normal signal(s) responsible for the onset of labor. Several lines of evidence suggest that at term such a signal has its origin within the amniotic cavity under normal circumstances. Fetal urine has been proposed to contain a factor capable of inducing the release of prostaglandins from amniotic cells and being such a signal.[17] This would explain the increased levels of prostaglandins in normal term labor. However, if the onset of preterm labor is triggered by bacterial products or inflammatory mediators present in the human decidua and not

in the amniotic cavity, prostaglandin levels in the amniotic fluid may not reach levels comparable to those achieved when the signal is of intra-amniotic origin.

The amniotic fluid concentrations of prostaglandins were not higher in nonlaboring women with PROM and intra-amniotic infection (group 3) than in women with PROM without intra-amniotic infections regardless of the presence or absence of labor (groups 2 and 1). At first, this finding would seem to argue against a role for prostaglandins in the onset of parturition associated with intra-amniotic infection since one would expect higher amniotic fluid concentrations in the infected group. However, this finding may simply reflect a temporal phenomenon. The production of prostaglandins by intrauterine tissues in response to bacterial infection may require a period of time for the generation of sufficient amounts of bacterial products or host inflammatory mediators to induce increased prostaglandin production. This hypothesis is supported by the difference observed between groups 3 and 4. Women in preterm labor with infection had higher amniotic fluid concentrations of prostaglandins than women with infection alone (group 4 versus group 3). These differences cannot be attributed to the presence of preterm labor alone as the amniotic fluid concentrations of prostaglandins were greater in women with preterm labor and infection (group 4) than in women with preterm labor without infection (group 2). This difference is unlikely to be attributable to the stage of labor at which the amniocentesis was performed because no differences in the amniocentesis-to-delivery interval were observed between groups 2 and 4. Although the mean gestational age in group 4 was significantly lower than that of group 2, it is unlikely that this accounted for the results observed because the earlier the gestational age the less likely there would be differences in amniotic fluid or plasma prostaglandin concentrations in women with preterm labor.[10, 11] Therefore the bias in the study is against the observed results. The difference in amniotic fluid prostaglandin concentration between groups 3 and 4 cannot be attributed to variation in quantitative or qualitative microbiology, as these were comparable (Tables III and IV). Therefore the data presented in this communication indicate that amniotic fluid concentrations of prostaglandins are elevated in preterm labor associated with intra-amniotic infection.

The mechanisms responsible for the increased concentration of prostaglandins in laboring women with intra-amniotic infections have not been established. The signal for the increased production of prostaglandins may be of bacterial origin. Lamont et al.[18] have found that bacterial products are capable of increasing the release of prostaglandin E_2 from amniotic cells. An alternative or complementary signal for the initiation of labor in the presence of infection may result from the activity of inflammatory mediators produced by the host in response to bacterial invasion. Interleukin 1, a fever and inflammatory mediator produced by mononuclear cells,[19, 20] could induce prostaglandin biosynthesis by intrauterine tissues. The ability of this hormone to stimulate the production of prostaglandins by other cell types has been demonstrated.[21-23]

We thank Professor M. J. N. C. Kierse from Leiden University, The Netherlands, for the kind gift of antibody against prostaglandin E_2 and Camille Grzyboski, C.M.T., for expert technical assistance.

Insulin resistance and abnormal ovarian responses to human chorionic gonadotropin in chronically anovulatory women

James Kustin, M.D., Ralph R. Kazer, M.D., David I. Hoffman, M.D., Robert T. Chatterton, Jr., Ph.D., John N. Haan, M.S., Orville C. Green, M.D., and Robert W. Rebar, M.D.

Chicago, Illinois

We studied the interrelationships between insulin resistance, obesity, and abnormal ovarian androgen secretion in chronically anovulatory women with clinical or biochemical evidence of hyperandrogenism. Four groups of six subjects each were studied: (1) normal weight (within 10% ideal body weight) anovulatory, (2) obese (>120% ideal body weight) anovulatory, (3) normal weight eumenorrheic, and (4) obese eumenorrheic. After dexamethasone suppression, human chorionic gonadotropin (2000 IU/1.5m^2 body surface area intramuscularly) was administered to each subject. Serum testosterone levels were subsequently determined hourly for 17 hours. On a separate occasion, an oral glucose tolerance test was administered to five subjects from each group. Serum glucose and immunoreactive insulin levels were determined before and after the ingestion of a standard 100 gm glucose load. As a group, the anovulatory women had higher ($p < 0.05$) basal testosterone levels (1005 ± 97 pg/ml) than did the ovulatory women (241 ± 21 pg/ml) (values ± SE). Obesity per se was not associated with increased basal testosterone levels. Testosterone levels rose in response to human chorionic gonadotropin ($p < 0.005$) only in obese anovulatory women, reached maximal levels after 3 hours, and subsequently remained stable. Basal immunoreactive insulin levels were elevated ($p < 0.05$) only in obese anovulatory women (52.4 ± 20 μU/ml) compared with obese eumenorrheic (8.7 ± 1.0 μU/ml), normal weight anovulatory (5.8 ± 2.4 μU/ml), and normal weight eumenorrheic (4.6 ± 0.4 μU/ml) women. Similarly, maximal increases in immunoreactive insulin levels after glucose ingestion were significantly greater ($p < 0.01$) in obese anovulatory women compared with other groups. Of note is the observation that maximal changes in testosterone observed within the first 3 hours after human chorionic gonadotropin and maximal changes in insulin were correlated ($r = 0.91$, $p < 0.01$). These data suggest that (1) both insulin resistance and an abnormal acute response to human chorionic gonadotropin are seen only in obese anovulatory women and (2) the degree to which these two abnormalities are manifested is clearly correlated. The mechanism(s) responsible for this interrelationship, as well as the underlying cause(s) of these biochemical defects, remain to be elucidated. (Am J Obstet Gynecol 1987;157:1468-73.)

Key words: Insulin resistance, abnormal ovarian responses, chronic anovulation

Several groups have demonstrated that insulin resistance in women with polycystic ovary syndrome correlates with the degree of hyperandrogenism.[1-3] This finding was originally described in obese subjects, but more recently has been documented in normal weight subjects who otherwise fulfilled strict criteria for the diagnosis of polycystic ovary syndrome, including perimenarcheal onset of oligomenorrhea, hirsutism, and an elevated ratio of luteinizing hormone (LH) to follicle-stimulating hormone (FSH).[3] Insulin resistance in women with polycystic ovary syndrome persists despite long-term ovarian suppression, suggesting that the insulin resistance and the resultant hyperinsulinemia may be responsible for the excess ovarian androgen secretion rather than vice versa.[4] This view has been substantiated further by in vitro studies, which have demonstrated the ability of insulin and related growth factors to stimulate androgen production in human ovarian stroma and theca.[5-21] It has been postulated that a local intraovarian hyperandrogenic environment may inhibit ovarian folliculogenesis.[6] This study was designed to define further the interrelationships among chronic anovulation, body weight, insulin resistance, and LH-dependent hyperandrogenism.

orrhea (<four periods/yr) who had clinical or biochemical evidence of hyperandrogenism. All subjects had been amenorrheic for at least 3 months before study and had not ingested any hormonal preparations during this time. Subjects with hypothalamic amenorrhea, hyperprolactinemia, thyroid disease, or primary adrenal disease were excluded. The subjects were divided into two groups on the basis of body weight. Obese amenorrheic subjects exceeded their ideal body weight as determined from the Metropolitan Life Insurance Company tables by 20%.[7] Normal weight amenorrheic subjects were within 10% of ideal body weight.

Twelve age-matched control subjects with regular menstrual periods (cycle length from 26 to 30 days, mean 28 days) were studied during the early follicular phase. Six subjects were obese and six were of normal weight. Basal LH, FSH, and prolactin levels were determined in all subjects before entry into the study. All subjects provided written informed consent before entry into the study.

Methods

Oral glucose tolerance test. All subjects were instructed to eat a 300 gm carbohydrate diet for 3 days before testing and were deprived of food after 6:00 PM the evening before testing. They were subsequently admitted to the Northwestern University Clinical Research Center at 7:00 AM, and an intravenous infusion of normal saline solution was started in a forearm vein.

Three blood samples were drawn at 10-minute intervals before the administration of a 100 gm oral glucose load at 8:00 AM. Subsequent blood samples were obtained 15, 30, 60, 120, and 180 minutes after glucose administration. Glucose and immunoreactive insulin levels were measured in all samples. Glucose concentrations were determined by an automated glucose oxidation method (Beckman autoanalyzer, Beckman Instruments, Palo Alto, California). Basal levels of glucose and insulin were calculated by averaging the values from the first three samples. Five subjects in each of the four study groups were studied in this manner.

Human chorionic gonadotropin (hCG) stimulation test. On a separate occasion, each subject received 2.0 mg of dexamethasone orally between 11:00 PM and midnight on the night before testing and 0.5 mg by mouth at noon, 6:00 PM, and midnight on the day of testing. After admission to the Clinical Research Center and insertion of an intravenous line kept open with normal saline solution, hCG (2000 IU/1.5m^2 body surface area) was administered intramuscularly at 1:00 PM. Blood samples were obtained every hour from 1:00 PM until 6:00 AM the next morning. Testosterone levels were determined in each sample by radioimmunoassay (RIA). All 24 subjects participated in this experiment.

Hormone assays. Circulating levels of immunoreactive insulin were measured by RIA as previously described.[8] Testosterone levels were also measured by RIA (Testosterone In Vitro Diagnostic Kit, Leeco Diagnostic, Inc., Southfield, Michigan). FSH, LH, and prolactin were measured by RIA as previously described.[9-11] The interassay coefficients of variation for the assays were as follows: insulin (10%), testosterone (6.5%), FSH (2.5%), LH (11.9%), and prolactin (8.9%). The intraassay coefficients of variation for the assays were as follows: insulin (5%), testosterone (4%), FSH (3%), LH (3%), and prolactin (3%).

Statistical analysis. All statistical analyses were carried out by means of one- or two-way analysis of var-

iance with subsequent Duncan's multiple range testing where appropriate. Data are expressed as means ± standard error of the mean. Linear regression analyses were carried out with the method of least squares.

Results

Collectively, the anovulatory subjects had a higher ($p < 0.05$) mean basal testosterone level compared with the eumenorrheic women (Table I). Individually, obese anovulatory women tended to have higher testosterone levels than normal weight anovulatory women, but the differences between the groups were not significant.

Basal glucose levels and those after glucose ingestion were similar in all four groups (Fig. 1). Basal immunoreactive insulin levels were increased ($p < 0.05$) only in obese anovulatory women when the mean values of

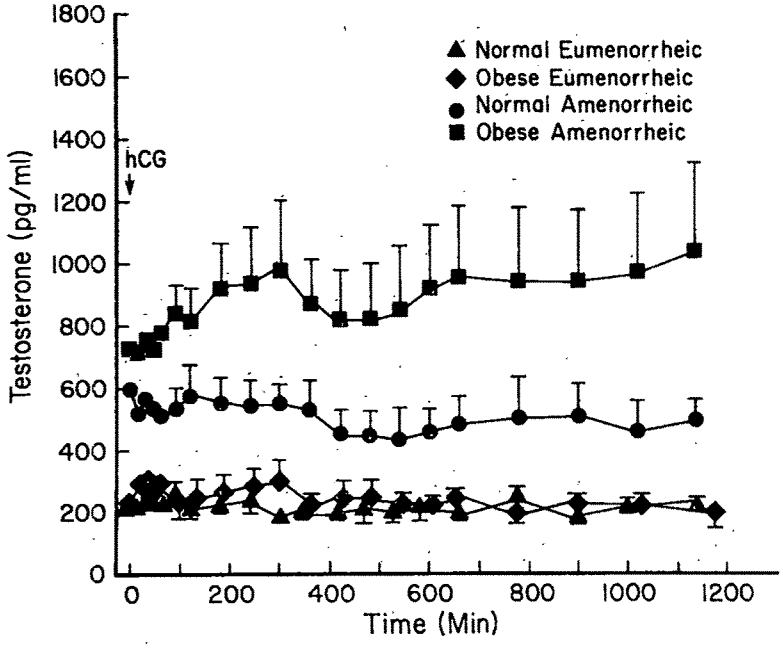

Fig. 4. Changes in serum testosterone over 17 hours in response to 2000 IU/1.5m^2 of intramuscular hCG administered at time zero in eumenorrheic and amenorrheic women further categorized by weight.

the four groups were compared (Table I). Two subjects in the obese anovulatory group, both of whom were extremely obese (173% and 214% ideal body weight, respectively), had particularly high basal immunoreactive insulin values of 67.7 and 77.2 μU/ml. Similarly, the mean maximal rise in immunoreactive insulin levels (maximal changes in insulin) after glucose was elevated ($p < 0.05$) only in obese anovulatory women (Fig. 2). Basal testosterone levels were correlated ($r = 0.48$, $p < 0.05$, Fig. 3) with basal immunoreactive insulin levels.

After hCG administration, testosterone levels rose ($p < 0.005$) in obese anovulatory women only. After 3 hours, testosterone levels had increased by an average

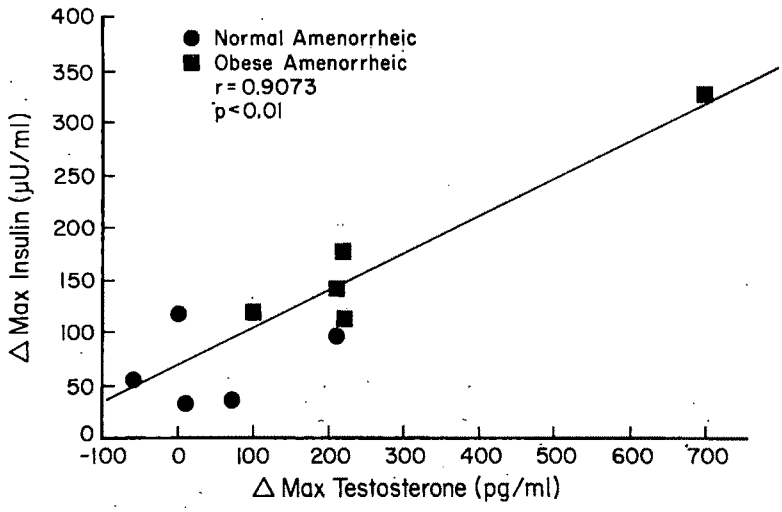

Fig. 5. The relationship between Δ_{max} testosterone over 3 hours after 2000 IU/1.5m² of intramuscular hCG and Δ_{max} insulin over 3 hours after a 100 gm oral glucose load in obese and normal weight amenorrheic women.

of 32% in obese anovulatory women but subsequently remained stable (Fig. 4). The maximal increase in testosterone during the first 3 hours after hCG (change in testosterone) was highly correlated with insulin ($r = 0.91$, $p < 0.01$) in the 10 anovulatory subjects who underwent both studies (Fig. 5).

Comment

It has been recognized for several years that hyperandrogenic, chronically anovulatory women frequently have mild insulin resistance.[2] Because many of these women are also obese, it is possible that the insulin resistance in such persons is simply a reflection of the well-known insulin resistance associated with obesity per se rather than a separate metabolic defect associated with ovulatory dysfunction and independent of body weight. Evidence exists, however, that at least a component of the insulin resistance in this group is not caused by obesity. When a group of obese subjects with polycystic ovary syndrome was compared with a significantly more obese control group, those with polycystic ovary syndrome still had more insulin resistance.[1] Furthermore, insulin resistance has been documented in nonobese subjects with polycystic ovary syndrome.[3] Finally, when both obese and nonobese women with polycystic ovary syndrome were compared with weight-matched control subjects, both polycystic ovary syndrome and obesity were associated separately with the presence of insulin resistance, although obesity seemed to play a much more important role.[12] Our data support the contention that obesity is the primary determinant of insulin resistance in hyperandrogenemic, anovulatory women in general. The fact that the normal weight, anovulatory subjects we studied had no evidence of insulin resistance may be because we did not use the same highly restrictive clinical and biochemical criteria used in almost all the other studies of polycystic ovary syndrome. Specifically, not all of the anovulatory subjects in our study had elevated LH/FSH ratios, perimenarcheal onset of menstrual irregularity, hirsutism, and documented morphologic ovarian abnormalities. Moreover, all but one of the studies cited used immunoreactive insulin responses to oral glucose ingestion as an index of insulin resistance, and it is unlikely that our findings resulted from differences in experimental technique. Our data confirm that chronic anovulation is a heterogeneous condition.

We and others have previously described the presence of hyperandrogenism in anovulatory subjects and its exaggeration in obesity.[12, 13] The present study adds further support to these findings.

Nevertheless, it is possible that basal levels alone are poor indexes of overall androgen production rates. Because we[13] and others[14-16] have shown that both obesity and hyperandrogenism are associated with decreased concentrations of sex hormone–binding globulin and a consequent increase in metabolic clearance rates[17] for circulating androgens, we elected to quantify the degree of LH-dependent ovarian hyperandrogenism in our subjects by administering hCG after dexamethasone suppression and measuring acute changes in testosterone levels. In designing this study, we were aware of data suggesting that hCG does not specifically stimulate the ovary[18, 20]; however, our goal was to suppress adrenal androgen production in all our subjects by the use of overnight dexamethasone suppression and thus minimize any adrenal contribution to the acute change in testosterone levels.

In contrast to basal testosterone data, which were similar in both obese and nonobese anovulatory subjects, the dynamic testing indicated that the obese subjects possessed unique responsiveness to hCG administration. Our data are in agreement with those of others who found correlations between the degree of insulin resistance and testosterone levels.[1-3, 12] The fact that this relationship remained apparent when hCG-stimulated rather than basal testosterone levels were compared with the degree of insulin resistance lends additional support to the hypothesis that the two abnormalities are related. It is important to keep in mind that the fact that a correlation exists between hyperandrogenism and insulin resistance in these subjects does not demonstrate a cause-and-effect relationship. In fact, the persistence of insulin resistance after medical castration suggests that the hyperandrogenism does not induce insulin resistance.[1] Although the elevation in immunoreactive insulin levels associated with insulin resistance may directly induce the ovarian overproduction of androgens, it is still possible that both abnormalities are caused by another as yet undetermined metabolic defect that results in both insulin resistance and an increase in ovarian androgen production. This latter possibility might partly explain why insulin resistance is not always observed in the nonobese anovulatory group.

Steroid synthetic and prostaglandin metabolizing activity is present in different cell populations from human fetal membranes and decidua

John R. G. Challis, Ph.D., D.Sc., and Michele Vaughan, B.Sc.
London, Ontario, Canada

We examined whether different cell subpopulations from human fetal membranes and decidua produce steroids (estrone and progesterone) and metabolize prostaglandins (prostaglandin $F_{2\alpha}$ to 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$ and if these changed with labor. Amnion, chorion, and decidua were obtained at elective cesarean section at term or at spontaneous labor. Cells were dispersed with collagenase and separated by density on discontinuous Percoll gradients. At cesarean section there was a major broad band of cells from amnion and chorion. This band contained most of the estrone sulfatase (estrone sulfate to estrone) activity. The 3β-hydroxysteroid dehydrogenase (pregnenolone to progesterone conversion) and prostaglandin $F_{2\alpha}$ metabolizing activities were present in these cells and those that migrated at greater Percoll densities. Amnion and chorion obtained after spontaneous labor had two major bands of cells. Estrone sulfatase was present in cells from both bands, whereas progesterone output from pregnenolone and prostaglandin $F_{2\alpha}$ metabolism predominated in the second band of cells with greater density. This pattern was particularly apparent in chorion. Dispersed cells from decidua tended to migrate throughout the gradient. In general, estrone sulfate to estrone conversion predominated in lighter cells whereas progesterone output from pregnenolone and prostaglandin $F_{2\alpha}$ metabolism predominated in cells of greater density. The output of progesterone from pregnenolone was significantly lower in cell preparations from chorion and decidua at spontaneous labor compared with cesarean section. We conclude that human amnion, chorion, and decidua contain distinct cell subpopulations based on Percoll migration and that in the membranes these change between cesarean section and spontaneous labor. Partial separation of estrone sulfatase from 3β-hydroxysteroid dehydrogenase and prostaglandin $F_{2\alpha}$ metabolizing activities has been demonstrated, which raises the possibility of paracrine interactions in vivo. (AM J OBSTET GYNECOL 1987;157:1474-81.)

Key words: Amnion, chorion, decidua, steroids, prostaglandins, parturition

Several groups of investigators have shown that human fetal membranes and decidua produce stimulatory prostaglandins (PG) in increasing amounts in association with the onset of human parturition.[1] The amnion and decidua are the major sites of primary PG output, whereas in vitro the chorion produces mainly 13,14-dihydro-15-keto-$PGF_{2\alpha}$ (PGFM). In addition, these structures produce steroids from exogenous precursors during late pregnancy and at parturition. We[2] and others[3] have shown that 3β-hydroxysteroid dehydrogenase activity (pregnenolone to progesterone conversion) predominates in the chorion and decidua. The activity of this enzyme decreases in decidua collected after labor of spontaneous onset.[4] Estrone sulfatase activity was also greater in the chorion and decidua compared with the amnion and increased significantly in tissues collected from patients at spontaneous labor compared with tissues collected at elective cesarean section.[5, 6]

Based on these observations, the hypothesis has been proposed that different cell populations in each of amnion, chorion, and decidua produce steroids and PGs, thereby allowing for paracrine interactions within these tissues in the maintenance of pregnancy and in the stimulus to birth. To explore this hypothesis, we have separated cell populations from amnion, chorion, and decidua on Percoll density gradients and examined whether the same or different cell populations in these tissues convert pregnenolone to progesterone (3β-hydroxysteroid dehydrogenase $\delta^{4,5}$ isomerase activity), estrone sulfate to estrone (estrone sulfatase activity), and $PGF_{2\alpha}$ to PGFM (15-hydroxyprostaglandin dehy-

drogenase $-\delta^{13,14}$ reductase activity). In addition, we have examined whether the cell populations showing these activities might change at the time of labor. Our results suggest that in amnion, chorion, and decidua, the steroid and PG metabolic activities are located in part in different cell subpopulations based on Percoll density separation. The distribution of cells changes between cesarean section and spontaneous labor, particularly in amnion and chorion.

Material and methods

Patients. The fetal membranes and adherent decidual tissue were collected from six patients at elective cesarean section at term without labor and from seven patients with term labor of spontaneous onset. In four of these women, tissues were collected after spontaneous vaginal delivery, and in three patients, the tissues were collected at cesarean section in labor. For analysis, results from these seven patients have been pooled. None of the patients received oxytocics.

Tissue preparation. The amnion was gently peeled away from the chorion. Decidua was scraped off the chorion as described previously.[7] Chorion and decidual tissue can be obtained in this way with <10% to 15% contamination. The tissues were then minced and dispersed into isolated cell preparations with the use of 0.05% collagenase and 0.003% deoxyribonuclease essentially as previously described.[7]

The mixed cells (2 ml suspension) were layered onto a discontinuous Percoll gradient, which was prepared essentially as described by Gibb and Lavoie,[8] in Krebs-Ringer bicarbonate buffer containing 1% albumin. The gradients were prepared in glass tubes to which successive 2.5 ml volumes of 60%, 40%, 20%, and 5% Percoll were added. The samples were centrifuged at 800 × g for 20 minutes at 4° C. After centrifugation, consecutive 1 ml fractions were collected from the top of the gradient to the bottom of the tube. A single drop was taken from each fraction to determine the density with a refractometer. The cells were centrifuged and washed three times at 4° C in Krebs-Ringer buffer containing 1% albumin. After the third wash, the cells were resuspended in 2 ml Krebs-Ringer bicarbonate buffer. An aliquot of cells was diluted with Hematall isotonic diluent, treated with 0.3% potassium cyanide (Hematall LA-Hgb reagent, Fisher Diagnostics, Orangeburg, New York) to lyse red blood cells, and then counted with a Coulter counter. Preliminary studies established that similar cell counts were obtained with a Coulter counter and by direct counting with a hemocytometer. Viability was assessed by the ability of the cells to exclude Trypan blue dye and was generally >85% to 90%. In preliminary experiments we established that single cell suspensions, which were essentially free of any aggregates, were present in mixed cell preparations and individual subpopulations obtained after Percoll gradient centrifugation.

An aliquot (500 μl) of the washed cells from each fraction off the Percoll column was then added to glass tubes containing pregnenolone (Steraloids Ltd.) or estrone sulfate (kindly provided by Dr. R. Hobkirk, Department of Biochemistry, University of Western Ontario), or $PGF_{2\alpha}$ (Upjohn Co., Ltd.). All three substrates were added at a concentration of 100 ng/100 μl of Krebs-Ringer bicarbonate buffer containing 1% albumin. The tubes were then incubated for 4 hours at 37° C in a shaking water bath. At the end of this period, the incubates were frozen and stored at −20° C until subsequent analysis. Progesterone, estrone, and PGFM were measured later in 0.5 ml aliquots by radioimmunoassays that have been described and validated previously.[2, 5, 7] Samples were acidified with citric acid before extraction of PGFM. PGFM and estrone were extracted twice with five volumes of diethyl ether; progesterone was extracted twice with five volumes of petroleum ether. Extraction recoveries were calculated by means of parallel tubes with the addition of approximately 1000 cpm [^{3}H] PGFM, progesterone, or estrone, as appropriate. Extraction efficiency was generally >85%, and all measurements were corrected for within assay recovery. The specificity and coefficients of variation for these assays on media from incubates of dispersed cells or explants of human fetal membranes and decidua have been previously described.[2, 5, 9] The combined inter- and intra-assay coefficients of variation in the present study ranged between 10% and 17%. Blank tubes containing the substrates pregnenolone, estrone sulfate, or $PGF_{2\alpha}$ but no cells were included in each incubation. The radioimmunoassay values in these tubes were subtracted from those in tubes containing cells to correct for cross-reactivities of the substrates in the different radioimmunoassays. The conversions to progesterone, estrone, and PGFM were expressed as net output per milliliter elution fraction from the Percoll column or as picograms per 10^5 cells for a 4-hour incubation period. Cell counts were made, and similar incubations were conducted in the presence of the different substrates on an aliquot of the mixed cell populations (100% cell fraction) before application to the Percoll columns.

Analysis of results. The output of progesterone, estrone, and PGFM was calculated for successive 1 ml elution fractions from the Percoll column. The sum of the separate cell counts in the different column fractions was expressed as a percentage of the total cells applied to the column to assess the losses of cells during the separation and washing procedures. The mean recovery of cells for all patients was 45.4% ± 5.7%, 45.4% ± 7.7%, and 34.3% ± 4.9% (SEM; n = 13) from amnion, chorion, and decidua, respectively. Be-

cause of the variability in cell counts between patients, the cell elution profiles were normalized by expressing the cell count in each fraction as a percentage of the cell count in the Percoll fraction with the maximum number of cells.

In some experiments the sum of progesterone, estrone, or PGFM output from the separate column fractions was calculated, corrected for the recovery of cells, and compared with the output of progesterone, estrone, and PGFM by the mixed cell populations. The output of progesterone, estrone, and PGFM in the initial 100% cell fractions and the sum of hormone outputs in the separated Percoll fractions were expressed per 10^5 cells. Comparison between the cesarean section and spontaneous labor groups was made by the Student *t* test after logarithmic transformation to correct for heterogeneity of variance.

Results

Net output of estrone, progesterone, and PGFM. The net accumulation of estrone, progesterone, and PGFM from estrone sulfate, pregnenolone, and $PGF_{2\alpha}$, respectively, during 4-hour incubations by the mixed cell preparations of different tissues is shown in Table I. Estrone output by amnion cells was less than that for chorion or decidua and did not change significantly with labor. The mean output of estrone from estrone sulfate by chorion and decidual cells increased with cells from patients in labor, although these differences were not statistically significant. The net accumulation of progesterone from pregnenolone was greater in chorion and decidua than in amnion. There was a significantly lower conversion of pregnenolone to progesterone by cell preparations of chorion and decidua obtained from patients at active labor compared with the conversion of pregnenolone to progesterone by these tissues at elective cesarean section ($p < 0.05$). The mean output of PGFM from $PGF_{2\alpha}$ by chorion cells was greater than that from amnion and decidua. There was no change in the output of PGFM From $PGF_{2\alpha}$ in cells from any tissue as a function of labor.

The effect of labor on estrone, progesterone, and PGFM output was also sought from the sum of separate conversions by the different fractions from the Percoll columns (Table II). In general, the results were similar to those obtained with the mixed cell preparations, although product formation per 10^5 cells tended to be higher. There was a significant decrease in the output of progesterone from pregnenolone by chorion and decidual cell preparations obtained after labor compared with the conversions by cells obtained from patients at elective cesarean section at term but not in labor (Table II; $p < 0.05$).

Elution profiles on Percoll

Amnion. The cells from amnion obtained at elective cesarean section eluted with a broad band of densities, ranging from 1.014 to 1.020 (Fig. 1, *a*). Cells in these fractions contained most of the estrone sulfatase activity. In contrast, cells forming progesterone from pregnenolone and PGFM from $PGF_{2\alpha}$ were distributed

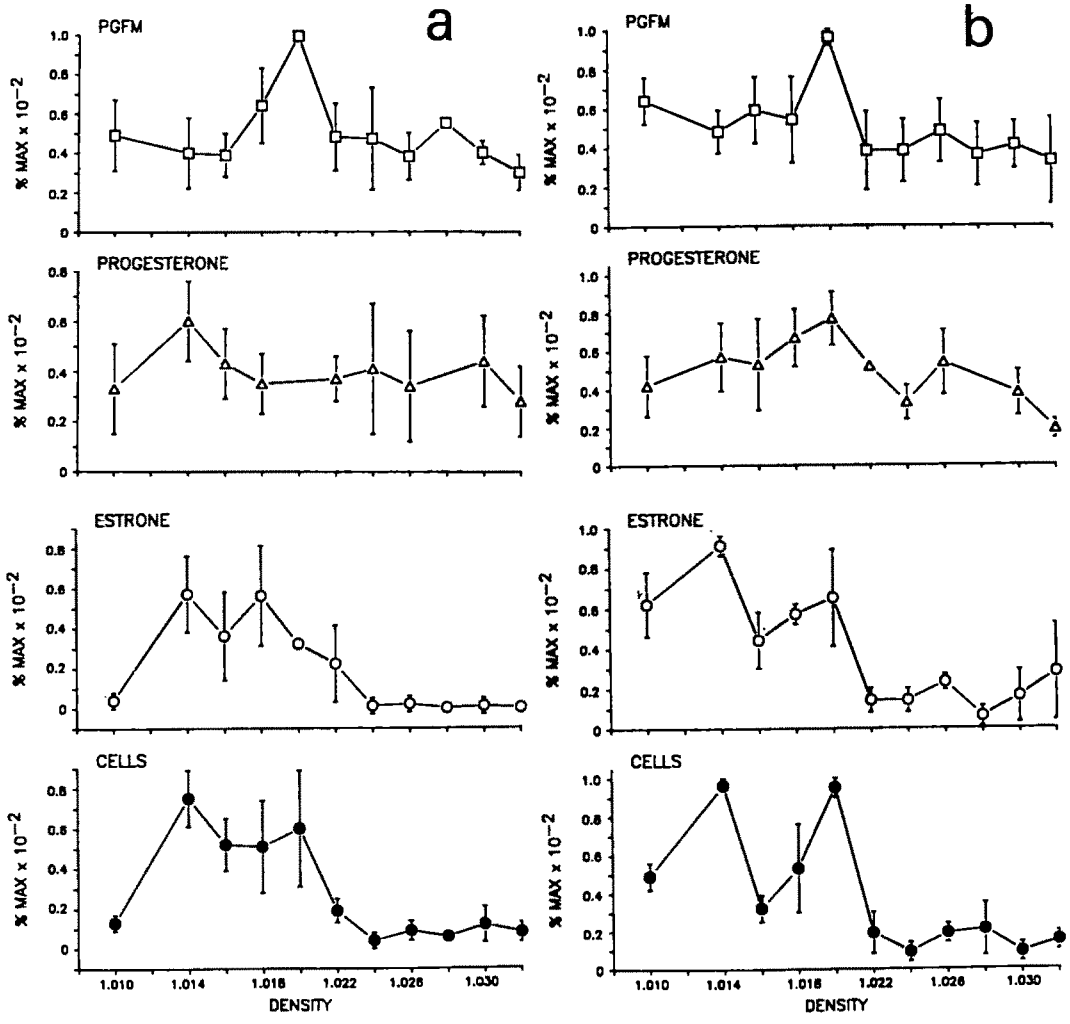

Fig. 1. The elution profiles on Percoll density gradients of cells (●) and PGFM formed from $PGF_{2\alpha}$ (□), progesterone formed from pregnenolone (△), and estrone formed from estrone sulfate (○) by amnion obtained from patients at term elective cesarean section **(a)** and at term spontaneous labor **(a)**. Values are mean ± SEM for six and seven patients, respectively.

throughout the density gradient. Cells from amnion obtained from patients in labor eluted with two major density peaks at 1.014 and 1.020 (Fig. 1, *b*). In general, the output of estrone and estrone sulfate, followed the same patten as cell distribution, with relatively little activity in cells migrating at densities >1.022. The cell bands that showed the highest conversion of pregnenolone to progesterone and $PGF_{2\alpha}$ to PGFM eluted at a density of 1.020. However, both of these activities were present in other cell fractions, which were distributed throughout the column (Fig. 1, *b*).

Chorion. Dispersed cells from chorion obtained from patients not in labor migrated predominantly as a single peak at densities of 1.012 to 1.014 (Fig. 2, *a*). Conversion of estrone sulfate to estrone was greatest by cells in this fraction. In contrast, the net accumulation of progesterone and PGFM from pregnenolone and $PGF_{2\alpha}$, respectively, was higher in cell fractions with greater densities.

Dispersed cells from chorion obtained at labor migrated with two major subpopulations at densities of 1.014 and 1.020, although smaller numbers of cells were eluted at other densities. The conversion of estrone sulfate to estrone followed a pattern similar to the elution profile of the cells, and the output of estrone was greatest in cell peaks at densities of 1.014 and 1.020. The output of progesterone from pregnenolone and PGFM from $PGF_{2\alpha}$ was greatest in cells that migrated at a density of 1.020, but these activities were also present in cells that migrated at heavier densities (Fig. 2, *b*).

Decidua. Decidual cells obtained at cesarean section migrated throughout the Percoll gradients. The output of estrone and estrone sulfate tended to be greater in

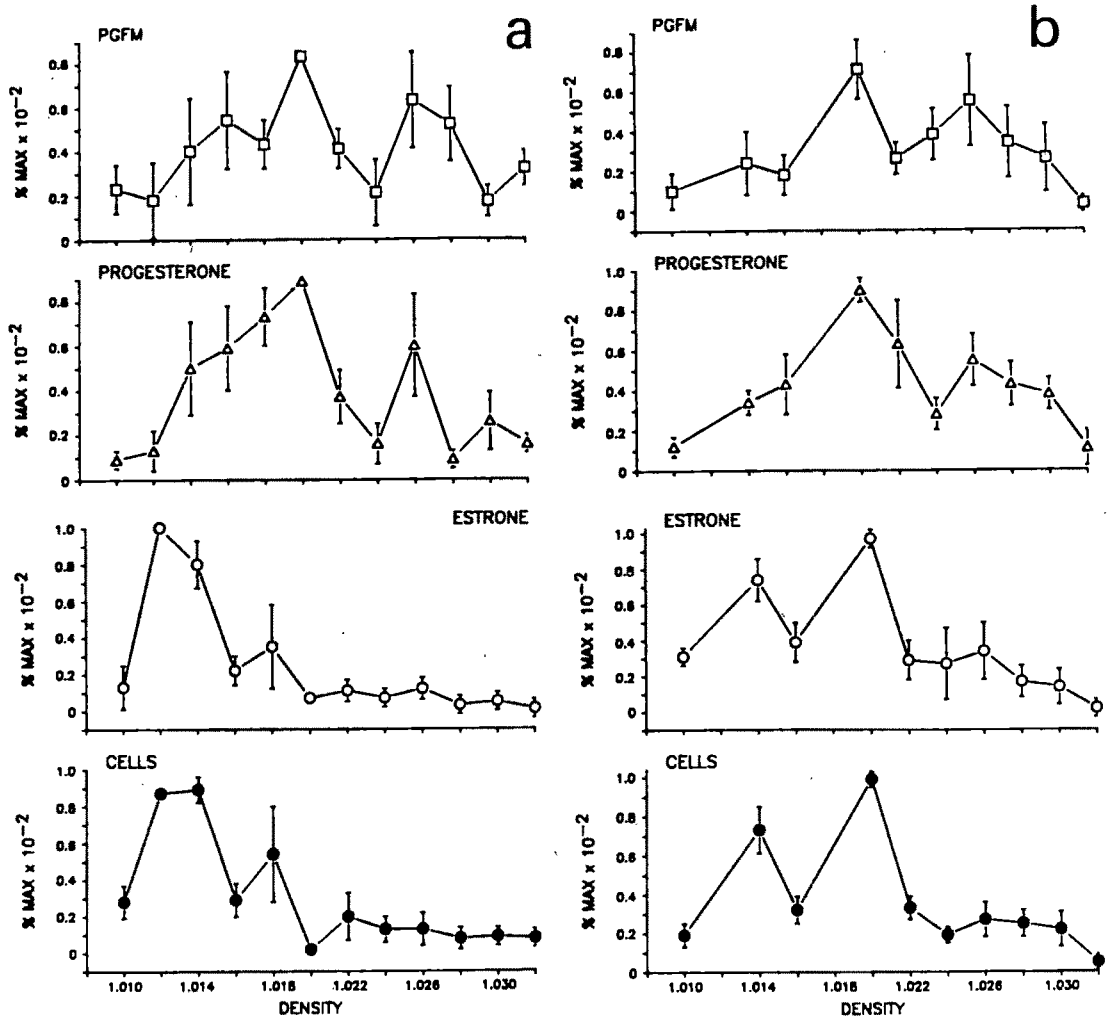

Fig. 2. The elution profiles on Percoll density gradients of cells (●) and PGFM formed from $PGF_{2\alpha}$ (□), progesterone formed from pregnenolone (△), and estrone formed from estrone sulfate (○) by chorion obtained from patients at term elective cesarean section **(a)** and at term spontaneous labor **(b)**. Values are mean ± SEM for six and seven patients, respectively.

the less dense fractions (1.012 to 1.018), whereas the net accumulation of progesterone or PGFM was greater in cells that migrated at higher densities (1.018 to 1.026). In general, the output of progesterone from pregnenolone and $PGF_{2\alpha}$ from PGFM showed a similar elution profile (Fig. 3, *a*). Decidual cells obtained from tissues at spontaneous labor were also distributed throughout the Percoll columns. The net accumulation of estrone from estrone sulfate was most evident in fractions of 1.010 to 1.020. The net output of estrone from estrone sulfate was less in the denser cell fractions. In contrast, there was little formation of progesterone or PGFM in the three lightest cell fractions. The net outputs of progesterone and PGFM were greatest in coincident subpopulations at a density of 1.020, although these products were also formed in all other cell fractions migrating at greater densities.

Comparison of hormone output in the mixed and separated cell fractions. The formation of estrone, progesterone, and PGFM by the separated cell fractions after correcting for cell losses through the column was compared with the output of these products in the initial 100% cell preparations. Although there was considerable variability between patients, the output of estrone from estrone sulfate was as much as 2.5 times greater in the separated cell preparations, whereas the average output of progesterone from pregnenolone and PGFM from $PGF_{2\alpha}$ was three to five times greater as the sum of the separated cell fractions (Table III). The differences between PGFM output by chorion ob-

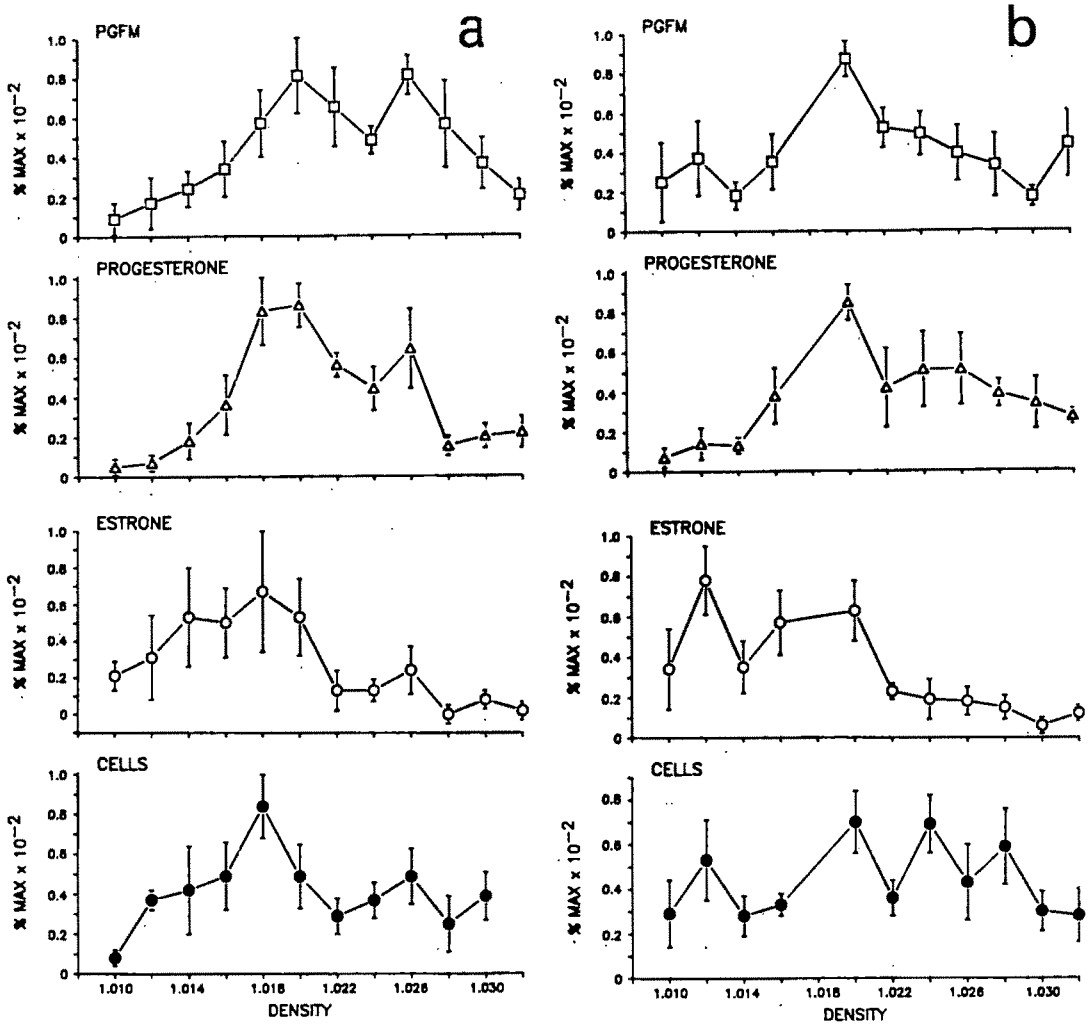

Fig. 3. The elution profiles on Percoll density gradients of cells (●) and PGFM formed from $PGF_{2\alpha}$ (□), progesterone formed from pregnenolone (△), and estrone formed from estrone sulfate (○) by decidua obtained from patients at term elective cesarean section (a) and at term spontaneous labor (a). Values are mean ± SEM for six and seven patients, respectively.

tained at elective cesarean section and spontaneous labor were significant ($p < 0.02$; t test).

Comment

The present study provides evidence that different cell populations based on density gradient separation can be obtained from human amnion, chorion, and decidua. In the membranes, the distribution of these cell subpopulations changes between cesarean section and spontaneous labor. Moreover, we found partial separation between cell fractions in the ability to convert estrone sulfate to estrone, pregnenolone to progesterone, and $PGF_{2\alpha}$ to PGFM. In addition, the net output of progesterone from pregnenolone by chorion and decidual cells decreased in preparations from women in active labor compared with patients at cesarean section at term but not in labor.

We have used Percoll to separate cell subpopulations. Preliminary studies established that individual cells without aggregates were present in the different fractions from the gradients. Differences between the fractions are attributable to differences in cell density, and the changes with labor are likely caused by an increase in cellular granular material or other intracellular inclusions rather than the appearance of a novel cell type. Further studies will require morphologic assessment of these subpopulations and the use of other physical methods of separation. After Percoll separation, cell viability was good, as indicated by the exclusion of Trypan blue dye. The differences in cell populations are

Table III. Ratio of the net accumulation of estrone, progesterone, and PGFM from exogenous substrates by the sum of separated cell fractions after Percoll with that by initial 100% cell fractions before Percoll

Tissue	*Product*	*Cesarean section (n = 6)*	*Spontaneous labor (n = 7)*
Amnion	Estrone	2.93 ± 1.31*	1.25 ± 0.23
	Progesterone	3.27 ± 0.87	4.72 ± 0.84
	PGFM	5.44 ± 1.71	8.29 ± 2.17
Chorion	Estrone	2.49 ± 1.28	1.89 ± 0.66
	Progesterone	2.74 ± 1.12	4.11 ± 1.19
	PGFM	2.13 ± 0.67	5.61 ± 1.05†
Decidua	Estrone	2.80 ± 1.36	2.21 ± 0.57
	Progesterone	3.45 ± 0.64	5.15 ± 1.75
	PGFM	4.82 ± 0.77	3.65 ± 0.83

*All values are mean ± SEM for the number of patients indicated; conversions to products are E_1S to estrone, pregnenolone to progesterone, and $PGF_{2\alpha}$ to PGFM.

†$p < 0.02$ versus cesarean section.

not likely to be the result of mechanical trauma because viability and cell recovery were similar with or without labor. Membranes collected from three patients at cesarean section in labor showed a distribution of cell subpopulations similar to that from four patients from whom tissue was collected after labor of spontaneous onset. Although the Percoll columns were set up as discontinuous gradients,[8] they were not maintained after centrifugation, and the results have been expressed to reflect the Percoll densities in successive 1 ml fractions containing cells.

The present study demonstrated the potential for precursor uptake and interconversion by intact cell preparations. We recognize that limitations of substrate and cofactor availability preclude calculation of enzyme kinetic parameters. However, in other studies we have shown the time and substrate concentration dependence of steroid conversions by intact cells. Moreover, net conversions even at substrate concentrations less than the Michaelis constant (K_m) of estrone sulfatase by intact cells have reliably predicted differences in enzyme activities between tissues obtained from patients at cesarean section or spontaneous labor.[5, 6, 10, 11]

The conversion of pregnenolone to progesterone was lower in initial 100% cell preparations and the sum of the separate cell fractions from chorion and decidua obtained at spontaneous labor compared with that at elective cesarean section at term. A similar decrease in pregnenolone to progesterone conversion at spontaneous labor has been reported with decidual explants.[1] These observations suggest that 3β-hydroxysteroid dehydrogenase $\delta^{4,5}$ isomerase (3β-hydroxysteroid dehydrogenase) activity may be reduced in these tissues at labor, which raises the possibility of local withdrawal of progesterone production from these intrauterine sources. Previous reports have shown that the activity of 3β-hydroxysteroid dehydrogenase is greater in chorion than in decidua or amnion,[2] which was confirmed in the present study. The mean conversion of pregnenolone to progesterone was greater in the sum of separated cell subpopulations than in the mixed cell preparations, which would be consistent with removal of an endogenous inhibitor by Percoll separation. Estrogens could be such inhibitors.[2, 12] The conversion of pregnenolone to progesterone in mixed cells is inhibited by estrone and estradiol,[2] and the major cell subpopulations converting estrone sulfate to estrone were separated from those converting pregnenolone to progesterone in the present study.

We have previously reported that the mean conversion of estrone sulfate to estrone[5] and estrone sulfatase activity[6] rises in chorion and decidua with labor. A similar trend was noted in the present study, although statistical significance was not achieved. Previous reports have indicated that estrone sulfatase activity is greater in chorion and decidua,[5] although activity is present in amnion.[5, 13] A similar distribution of estrone sulfatase was found in the present study. Steroid sulfatase activity with dehydroepiandrosterone sulfate as a substrate was not found in amnion, although is present in chorion.[8, 13, 14]

We also confirmed the very low conversion of $PGF_{2\alpha}$ to PGFM (15-hydroxyprostaglandin dehydrogenase) in amnion and greater output of PGFM in chorion.[15] It was previously reported that the output of PGFM by chorion cells from endogenous precursors increased at the time of labor.[7] The present study suggests that this is likely caused by increased formation of $PGF_{2\alpha}$ in chorion, since our results indicate that the conversion of $PGF_{2\alpha}$ to PGFM did not appear to change with the onset of labor. In general, the output of PGFM from $PGF_{2\alpha}$ was greater as the sum of activities from separated cell subpopulations compared with the mixed cell fractions, which might suggest that this conversion is influenced by an inhibitory component. The potential exists for 15-hydroxyprostaglandin dehydrogenase regulation during pregnancy. 15-Hydroxyprostaglandin dehydrogenase in the fetal lung[16, 17] and uterus[18] of a rabbit increases during pregnancy. It is possible that the $PGF_{2\alpha}$ to PGFM conversion is influenced by steroids of pregnancy, including progesterone, and is also regulated in the mixed cell preparations of human fetal membranes in vitro.

This study is the first report to separate cell subpopulations from human fetal membranes and decidua that convert estrone sulfate to estrone from cell populations that convert pregnenolone to progesterone and $PGF_{2\alpha}$ to PGFM. Estrone sulfatase activity was present in cells migrating at lighter densities, whereas pro-

gesterone and PGFM formation from pregnenolone and $PGF_{2\alpha}$, respectively, were present more in cells that migrated at greater density. In general, cells converting pregnenolone to progesterone and $PGF_{2\alpha}$ to PGFM migrated with similar densities, although the present study does not reveal whether the same or different cell groups are involved in those conversions. We expressed our results on the basis of successive fractions from the Percoll gradient and did not establish whether the enzymatic conversions were attributable to all the cells in any one subpopulation or to a variable percentage of them. Gibb and Lavoie[8] expressed their results in a similar manner and also showed that 3β-hydroxysteroid dehydrogenase activity in chorion cells was distributed widely through the gradient. In that report, dehydroepiandrosterone sulfatase activity was measured and was found to predominate in lighter cells, resembling the pattern with estrone sulfatase activity in the present study.

The significance of the change in distribution of cell populations with labor requires further study. It is of interest that the second band of cells in the chorion and amnion actively convert estrone sulfate to estrone, and this activity increases with labor.[5, 6] The results of the present report raise clearly the possibility of paracrine or autocrine interactions between cell types in amnion, chorion, and decidua. Steroids affect prostaglandin cyclooxygenase and 15-hydroxyprostaglandin dehydrogenase activities,[18] and estrogen may inhibit 3β-dehydroxysteroid dehydrogenase activity.[12] Furthermore, the potential for local increases in estrogen output and decreases in progesterone formation from pregnenolone raises the possibility that these may occur in the absence of alterations in circulating steroid hormone concentrations.[19] Such changes may exert influences on agonist receptor populations and gap junction formation and thereby contribute to pregnancy maintenance and birth.

We thank Carole Brunette-Cahill, Lori Power, and Nan Cumming for their technical assistance, and Drs. J. Patrick, F. Fellows and G. Vilos for providing tissues.

Effects of calcium entry blocker (nicardipine) tocolysis in rhesus macaques: Fetal plasma concentrations and cardiorespiratory changes

Charles A. Ducsay, Ph.D., Jeffry S. Thompson, B.S., Anne T. Wu, Ph.D., and Miles J. Novy, M.D.

Loma Linda and Palo Alto, California, and Beaverton and Portland, Oregon

Tocolytic doses of nicardipine, a dihydropyridine calcium entry blocker, were administered to chronically catheterized rhesus monkeys between days 128 and 132 of gestation. During periods of spontaneous uterine contractility, a 500 μg nicardipine bolus was injected intravenously, and this was followed by continuous infusion (6 μg/kg/min) to the mother for 1 hour. Uterine activity (amniotic fluid pressure) and maternal heart rate and blood pressure were monitored continuously. Paired maternal and fetal blood samples were drawn at frequent intervals to monitor pH, Po_2, Pco_2, and plasma nicardipine concentrations. Peak maternal nicardipine concentrations ranged from 175 to 865 ng/ml while peak fetal levels ranged from 7 to 35 ng/ml. Fetal heart rate and blood pressure were unaffected. However, fetuses became acidotic (pH 7.26 ± 0.01 versus 7.33 ± 0.01) and hypoxemic (Po_2 16.0 ± 3.2 versus 24.5 ± 2.0 mm Hg) after maternal nicardipine treatment ($p < 0.01$). Despite the fact that maternal nicardipine treatment exerted a significant tocolytic effect, the undesirable fetal side effects are of concern and deserve further investigation. (Am J Obstet Gynecol 1987;157:1482-6.)

Key words: Uterine contractility, nicardipine, fetus, rhesus monkey

Calcium entry blockers are potent smooth muscle relaxants and are widely used clinically for treatment of cardiovascular disorders.[1] More recently, a number of reports have suggested the potential use of calcium entry blockers as uterine tocolytic agents.[2, 3]

Little information is currently available regarding the effect of tocolytic doses of calcium entry blockers on fetal or neonatal well-being. Limited studies in the human have failed to detect any major adverse effects of maternal administration of the dihydropyridine calcium entry blockers on neonatal outcome.[4, 5] However, delivery of viable fetuses with normal Apgar scores is only a gross indicator of fetal safety. The extent of transplacental passage of calcium entry blockers and their fetal metabolic or hemodynamic effects have not been adequately evaluated in human pregnancy for obvious ethical reasons.

More complete animal studies have documented a beneficial tocolytic effect of nifedipine and nicardipine. However, a number of these studies have also revealed a wide range of deleterious side effects. Decreases in maternal arterial pressure, uterine blood flow, fetal arterial pressure, and fetal-oxygenation have been reported in studies in pregnant rabbits and sheep.[6-8] Experiments in the pregnant rhesus monkey have demonstrated a significant compromise of fetal oxygenation when tocolytic doses of nifedipine were administered to the mother.[9] The effects of nicardipine, a calcium entry blocker that also has a potent phosphodiesterase inhibitory action, have not been studied previously in a primate animal model.

The present study was designed to extend our observations on the fetal cardiorespiratory effects of maternal calcium entry blocker administration and to quantitate the transplacental passage of nicardipine in the rhesus macaque during late gestation.

Material and methods

Operation. Four rhesus monkeys *(Macaca mulatta)* between 128 and 132 days' gestation (term = 167 days) were used in the present study. Surgical procedures were performed by methods previously described in detail.[10] Briefly, with the animals under halothane anesthesia, polyvinyl catheters were implanted in the ma-

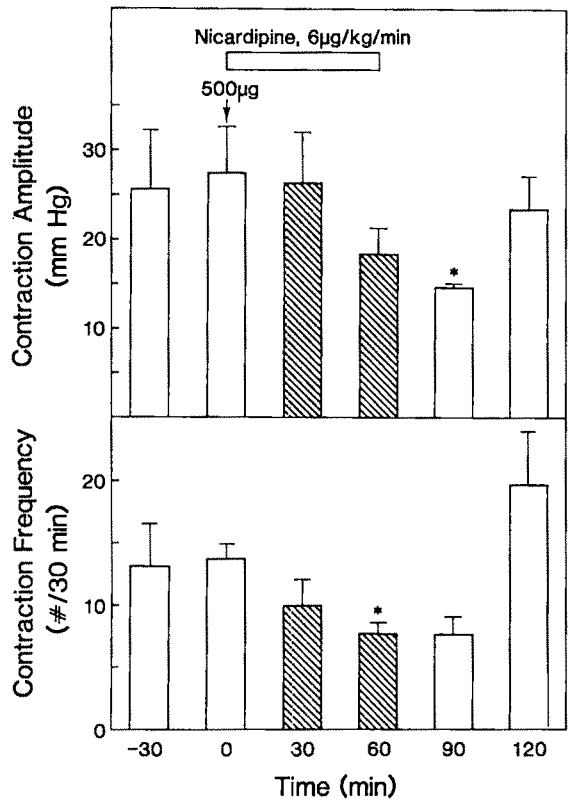

Fig. 1. Effect of maternal nicardipine administration on mean contraction amplitude and contraction frequency. *Cross-hatched bars* (t_{30}, t_{60}) represent sampling intervals during maternal nicardipine treatment. All values are mean ± SEM (n = 4). *Asterisk* indicates significant difference from control values (t_{-30}, t_0) ($p < 0.05$).

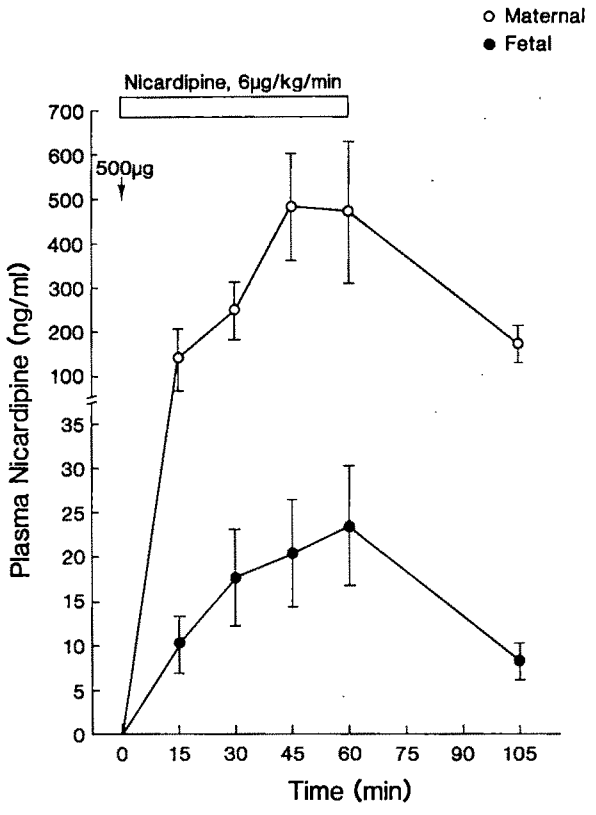

Fig. 2. Maternal and fetal plasma nicardipine concentrations after maternal nicardipine administration. All values represent mean ± SEM (n = 4). Maternal nicardipine (500 μg bolus followed by 6 μg/kg/min intravenous infusion) treatment was begun at t_0 and discontinued at t_{60}.

ternal femoral artery and vein, the fetal carotid artery and jugular vein, and the amniotic fluid cavity. Electrocardiogram electrodes were also attached to the fetus.

Study protocol. Three to four days after operation, during periods of spontaneous uterine contractility, a 500 μg bolus of nicardipine hydrochloride (Syntex Laboratories, Palo Alto, California) in buffer was injected between uterine contractions into the maternal venous catheter, and this was followed by a continuous infusion (6 μg/kg/min) for 1 hour by a Harvard infusion pump. Uterine contractility (amniotic fluid pressure) and fetal and maternal heart rate and arterial pressure were monitored continuously throughout the study. Paired fetal and maternal arterial and amniotic fluid samples were collected at 15- to 30-minute intervals 1 hour before, during, and 1 hour after maternal nicardipine administration. Maternal and fetal arterial pH, P_{CO_2}, and P_{O_2} were determined with a Radiometer blood gas analyzer. Samples for nicardipine quantitation were stored at −70° C until analysis by a modified capillary gas chromatography–electron-capture detection method.[11]

Statistical analysis. Differences between means of control and experimental measurements were tested by two-way analysis of variance and Duncan's multiple-range test. Values are expressed as means ± SEM.

Results

Uterine contractility. The effect of maternal nicardipine administration on uterine contractility is illustrated in Fig. 1. Mean contraction amplitude decreased within 30 to 60 minutes after nicardipine infusion was started and was significantly lower ($p < 0.05$) than control values by 90 minutes after the beginning of treatment (Fig. 1). Contraction frequency followed a similar pattern in which values declined from a control mean of 15.0 ± 2.5 to 10.1 ± 1.9 contractions per 30 minutes at 30 minutes after the start of the nicardipine infusion (Fig. 1). Values declined further at 60 minutes to 7.5 ± 1.5 contractions per 30 minutes, which was a statistically significant change from the control value ($p < 0.05$). The cumulative tocolytic effect was apparent at the end of the nicardipine infusion and was sustained for 30 minutes after the infusion was terminated. The effect was transient, however, since values for both

†$p < 0.01$.

mean contraction amplitude and contraction frequency returned to control levels within 60 minutes after discontinuing nicardipine (Fig. 1).

Maternal and fetal hemodynamics. Mean maternal arterial pressure declined significantly ($p < 0.05$) from control levels of 93.6 ± 1.7 to 84.0 ± 2.1 mm Hg at 60 minutes (Table I). Pressure remained depressed at 90 and 120 minutes but the difference was not significant. Compensatory maternal tachycardia was observed with an elevation in maternal heart rate at 60 minutes that was not significant (Table I). Values returned to control levels in the hour after nicardipine infusion. A slight but nonsignificant decline in fetal mean arterial pressure was observed after maternal nicardipine infusion (Table I). Fetal heart rate was unaffected (Table I).

Maternal and fetal blood gases. Maternal arterial P_{O_2}, P_{CO_2}, and pH did not change in response to nicardipine treatment (Table II). In contrast, fetal blood gas values were significantly affected. Fetal arterial pH declined from control values of 7.331 ± 0.009 to significantly lower levels after infusion (Table II). The maximal decline in fetal arterial pH was observed at 90 minutes with a mean value of 7.268 ± 0.016 ($p < 0.01$) (Table II).

Fetal arterial P_{CO_2} increased dramatically after the start of nicardipine treatment with significant differences observed at 60 and 90 minutes. Peak values, which were observed at 90 minutes, were significantly higher than control levels (45.2 ± 4.2 versus 35.5 ± 2.4 mm Hg, respectively) ($p < 0.01$) (Table II). The most striking alterations were observed in fetal arterial P_{O_2}. Values were significantly depressed throughout the period of nicardipine treatment. The maximum decline in fetal arterial P_{O_2} was observed at 60 minutes (16.8 ± 2.2 versus 24.7 ± 2.1 mm Hg for control) ($p < 0.01$) (Table II).

Maternal and fetal plasma nicardipine concentrations. Maternal and fetal plasma nicardipine concentrations are illustrated in Fig. 2. Nicardipine was readily detectable in fetal blood within 15 minutes after a maternal intravenous bolus injection of 500 μg. During the constant 1-hour infusion nicardipine concentrations in fetal blood rose nearly in parallel with levels in maternal blood. Peak maternal plasma nicardipine concentrations were observed at 45 and 60 minutes with peak values ranging from 175 to 865 ng/ml. Fetal concentrations peaked at 60 minutes with maximum values ranging from 7 to 35 ng/ml. Fetal plasma concentrations did not exceed 6% of maternal levels. When the intravenous infusion was discontinued maternal and fetal plasma nicardipine concentrations declined in a

rapid and parallel fashion and reached 35% of maximum levels within 45 minutes. Nicardipine was essentially undetectable in the amniotic fluid.

Comment

The results of the present study confirm and extend our previous observations on the effects of tocolytic doses of calcium entry blockers in the pregnant rhesus monkey.[9] The two studies together clearly demonstrate that although calcium entry blockers of the dihydropyridine type are effective tocolytic agents in primates, other inherent problems may limit their clinical utility. Specifically, deleterious alterations are observed in fetal blood gas parameters. Fetal arterial pH, P_{CO_2}, and P_{O_2} were all markedly altered in response to maternal nicardipine administration. The question remains, what are the factor(s) responsible for these changes?

We had previously speculated that because of the high degree of binding to plasma protein, calcium entry blockers of the dihydropyridine type would likely be limited in their extent of placental transfer.[9] To our knowledge, the present study is the first to quantitate fetal levels of nicardipine in the primate fetus after maternal administration. Although variable, fetal levels never exceeded 6% of maternal plasma concentrations. Transplacental passage of nicardipine therefore is minimal in the primate. The low circulating levels of nicardipine in the fetus did not have a significant effect on fetal cardiovascular dynamics. Fetal heart rate remained unchanged and there was a minimal tendency for fetal mean arterial pressure to decline (Table I).

In the present study it is difficult to assess the effect of the decline in maternal mean arterial pressure on placental perfusion, since blood flow measurements were not made. Mean arterial pressure declined only 10% from control values after nicardipine administration. Golichowski et al.[12] used a 30-minute constant infusion of nifedipine to pregnant sheep and observed a 12% fall in maternal blood pressure at a dose of 10 μg/kg/min. Veille et al.[13] administered a bolus injection of nifedipine (20 to 40 μg/kg) to pregnant pygmy goats and observed a 10% decline in maternal arterial pressure and a transient fall in uterine blood flow in some animals. In a similar study of pregnant ewes, Harake et al.[8] measured a 21% drop in uterine blood flow in response to nifedipine (10 μg/kg/min). Since uterine vascular resistance was unchanged, the drop in uterine blood flow was attributed solely to the maternal hypotensive effect of the calcium entry blocker. Fetal arterial pH and oxygen saturation also decreased. Other studies in pregnant rabbits given nicardipine (36 μg/kg/min) also demonstrated an appreciable decline in uterine blood flow that was related to maternal hypotension.[14] It was reported that maternal nicardipine administration can alter the distribution of fetal cardiac output without changing total cardiac output.[8, 15] Increases in brain and myocardial blood flow but not in umbilical blood flow were observed in chronically catheterized fetal sheep.[8, 15]

Although species differences may exist, one would expect similar mechanisms to operate in the rhesus monkey. However, in a previous study we observed that with continuous infusions of nifedipine (3 μg/kg/min) (without a preinfusion bolus) no change in maternal arterial pressure occurred.[9] Despite this fact, the decline in fetal arterial pH and P_{O_2} that was observed was similar in magnitude to the changes observed with nicardipine administration in the present study. Parisi et al.[7] found that nicardipine (20 μg/kg/min) administered to hypertensive ewes in doses sufficient to render them normotensive also resulted in fetal hypoxemia and acidosis. In some instances, fetal death occurred. The study by Parisi et al.[7] also demonstrated that angiotensin II vasoconstriction was reversed by nicardipine in the systemic and uterine vessels but not in the placenta. It seems logical then to conclude that the compromise in fetal oxygenation observed in most studies is due in part to a decrease in uterine blood flow in response to maternal hypotension but that other factors (for example, redistribution of uteroplacental blood flow or shunting producing a maternal-fetal perfusion imbalance) likely play an important role.

Earlier studies in which nifedipine was used to treat premature labor in women documented a marked tocolytic effect with no apparent compromise of neonatal outcome.[4, 5] The present study and other observations in experimental animals cast a shadow of concern over the use of these agents for routine clinical tocolysis.[7-9] A major problem in comparing clinical and experimental studies, apart from obvious species differences, is the dosage and route of administration. Animals in the present study received a 500 μg intravenous bolus followed by a continuous infusion of 6 μg/kg/min for 1 hour. This equals a total dose of approximately 2.7 mg per rhesus monkey (average weight = 6 kg) or 0.45 mg/kg. The common dosage of calcium entry blocker used in clinical trials is 20 to 30 mg administered orally or sublingually every 6 to 8 hours or 0.40 to 0.60 mg/kg. Therefore the amount of nicardipine used in this study is in the range recommended for human use. Although the majority of clinical studies use oral administration instead of intravenous injection, maternal uptake of calcium entry blockers is quite rapid. Ramesch and Sommer[16] demonstrated detectable levels of nifedipine in the maternal circulation 6 minutes after oral administration, with maximum concentrations reached after 1 hour.

It is noteworthy that in studies in pregnant sheep, the fetal-to-maternal plasma concentration ratios were 0.3 to 0.4 during nifedipine infusions.[8] In the monkey

the nicardipine ratio was <0.1. On the basis of placental type, one would predict the monkey placenta to be more permeable, but earlier studies have suggested the important effect of protein binding on placental transfer of calcium entry blockers.[2] Nifedipine and nicardipine are both dihydropyridine derivatives but nicardipine also has a potent phosphodiesterase inhibitory action.[17] Although nicardipine has a slower onset of action it is more potent than nifedipine in relaxing isolated strips of human pregnant myometrium.[17]

In conclusion, the present study demonstrates that nicardipine crosses the placenta in measurable quantities and may adversely affect fetal oxygenation by a variety of mechanisms. Calcium entry blockers are potentially useful uterine tocolytic agents, but more detailed studies of their hemodynamic and metabolic side effects in the fetus are required before this potential can be fully and safely realized.

We wish to acknowledge the expert technical assistance of Michael J. Cook. In addition, we wish to thank Dr. Milan Henzl at Syntex Research for his invaluable assistance.

Temporal changes in uterine activity and prostaglandin response to RU486 in rhesus macaques in late gestation

George J. Haluska, Ph.D., Frank Z. Stanczyk, Ph.D., Michael J. Cook, and Miles J. Novy, M.D.

Beaverton and Portland, Oregon

Progesterone withdrawal as a mechanism of parturition in primates is controversial because maternal, fetal, and amniotic fluid progesterone concentrations do not decrease before parturition. We therefore studied the effects of RU486 on uterine activity and amniotic fluid prostaglandins in four rhesus macaques implanted with amniotic fluid and maternal vascular catheters and with fetal electrocardiogram and uterine electromyogram electrodes at 119 to 124 days' gestation (term = 168 days). Uterine electromyogram, intra-amniotic pressure (hourly contraction area, mm Hg · sec/hr), and fetal electrocardiogram were monitored continuously. After a stabilization period (6 to 9 days) RU486 was administered orally (20 mg/kg/day) at 1000 hours for 3 days. Uterine activity increased from basal levels (<4000 mm Hg · sec/hr) 8 hours after the first dose of RU486, reaching levels of 12,000 mm Hg · sec/hr. A sustained increase in uterine activity (13,000 to 30,000 mm Hg · sec/hr) was observed for 48 hours before cesarean section with little or no cervical effacement or dilatation. Increases in amniotic fluid prostaglandin $F_{2\alpha}$, 6-keto-prostaglandin $F_{1\alpha}$, 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$, and 11-deoxy-13,14-dihydro-15-keto-11β, 16ε-cycloprostaglandin E_2 occurred 40 hours after the onset of increased uterine activity. In contrast, amniotic fluid prostaglandins in the control animals delivering at term (n = 4) increased 24 to 48 hours before significant increases in uterine activity occurred. Control animals but not those given RU486 demonstrated a progressive nocturnal peak in uterine activity before delivery. Progesterone receptor blockade stimulates intense preterm uterine activity but not the orderly sequence of changes in prostaglandins and cervical status observed during normal parturition. (Am J Obstet Gynecol 1987;157:1487-95.)

Key words: RU486, prostaglandins, uterine activity, progesterone receptors

The inhibitory effect of progesterone on the pregnant myometrium is well documented in lower mammals, and in those species progesterone withdrawal is a necessary step in the sequence of events leading to spontaneous labor and successful delivery of a viable fetus.[1] However, progesterone withdrawal, as a mechanism for parturition in primates, is controversial because of sustained antepartum levels of this hormone in maternal and fetal blood and in amniotic fluid.[2, 3]

The availability of synthetic progestin antagonists provides a useful tool to investigate the effects of functional progesterone withdrawal on hormonal control of the initiation of parturition. RU486 is a potent synthetic 19-norsteroid that interacts with the progesterone receptor and antagonizes the action of this hormone in all species studied so far. Preliminary investigations in monkeys and human beings indicate that the administration of RU486 effectively induces abortion in early pregnancy[4, 5] and is somewhat less effective for induction of delivery during late gestation in nonhuman primates.[4]

The nature of the biologic effects of RU486 on the pregnant primate uterus and cervix have not previously been described. We therefore administered RU486 to chronically catheterized rhesus macaques during late pregnancy and report here its effects on uterine contractility, cervical ripening, and the associated changes in amniotic fluid prostaglandins and maternal plasma steroid hormone concentrations.

Material and methods

Animals. Timed pregnant rhesus macaques *(Macaca mulatta)* were obtained from the breeding colony at the Oregon Regional Primate Research Center. At approximately day 110 of pregnancy, the animals were conditioned to a jacket and tether system.[6] The animals were maintained on their normal diet of 25% protein Purina Monkey Chow and fruit throughout the conditioning and experimental periods.

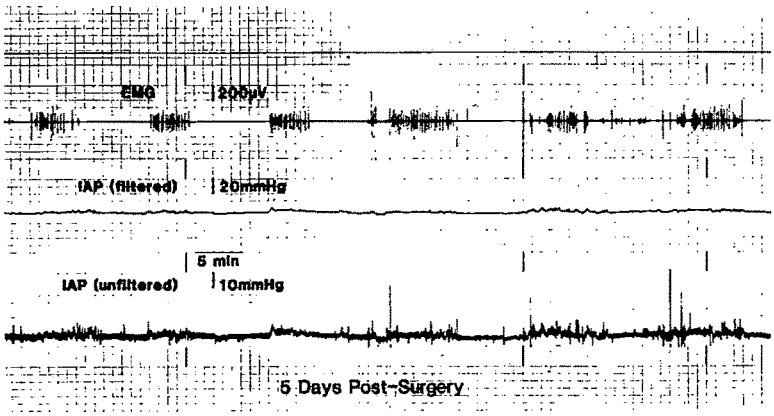

Fig. 1. Section of a representative recording from the quiescent uterus of a rhesus macaque at 5 days after operation showing electromyogram *(EMG)* and intra-amniotic pressure *(IAP)* during a 1-hour period. The uteri of all the animals in this study returned to this state of quiescence after the initial postoperative increase in activity and remained quiescent until treatment with RU486 or spontaneous delivery.

Nine animals were used in this study. Maternal femoral arterial and venous catheters, two open-ended intra-amniotic pressure catheters, two sets of myometrial bipolar electromyographic electrodes, and fetal electrocardiographic electrodes were implanted in each animal in the surgical suite at the research center according to the method of Novy et al.[7] All animals received terbutaline sulfate (1 mg/150 ml 5% dextrose in water over 3 to 5 hours, b.i.d.) for 24 to 48 hours after operation, to control surgically induced uterine activity, and indomethacin (50 mg orally b.i.d.) for 48 hours after operation, as an analgesic. Operation took place on days 119 to 124 of gestation for RU486-treated animals and on days 116 to 140 for control animals (term = 168 days). Six to nine days after operation the five experimental animals received RU486 at a dose of 20 mg/kg/day for 3 days at 10:00 AM each day. The fetuses were delivered by cesarean section 72 hours after the initiation of RU486 treatment. The four control animals received no treatment except for vehicle control in the diet and postoperative care, and they delivered spontaneously on days 156 to 167 after being monitored in the tether assembly for 24 to 45 days.

Uterine activity and cervical status. Uterine activity (electromyographic and intra-amniotic pressure) was recorded continuously on a Hewlett-Packard eight-channel recorder beginning immediately after operation until cesarean section or spontaneous delivery and was simultaneously monitored with a TEK-31 programmable calculator, as described by Ducsay et al.[8] Uterine contractility is expressed as the area under the contraction curve per hour (hourly contraction area in mm Hg · sec/hr). Electromyographic activity was not quantified but is described qualitatively relative to amniotic fluid pressure.

The cervix was palpated vaginally immediately after operation, before each dose of RU486 (time 0, +24, and +48 hours), and before cesarean section (+72 hours). Consistency, effacement, and dilatation of the cervix were recorded at each examination.

Collection and storage of plasma and amniotic fluid samples. Maternal plasma and amniotic fluid samples were collected every 3 days and then every 12 hours (9:00 AM and 9:00 PM) for 72 hours before and after RU486 administration in experimental animals. Plasma and amniotic fluid samples were collected every 3 days for control animals until parturition was imminent and every 12 hours at 9:00 AM and 9:00 PM thereafter. Plasma and amniotic fluid samples were frozen after centrifugation and stored at −20° C. All samples were assayed within 1 month after collection.

Radioimmunoassays. Maternal plasma was used to measure progesterone, estradiol and estrone levels according to the method of Resko et al.,[9, 10] and cortisol according to the method of Krey et al.,[11] with antisera obtained from Radioassay Systems Laboratories, Inc., Carson, Calif. The cross-reactivity of pure RU486 in the present progesterone assay system was <0.01%.

Amniotic fluid samples were also used to measure concentrations of prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$ (PGFM), 6-keto-prostaglandin $F_{1\alpha}$ (6-keto-$PGF_{1\alpha}$), and 11-deoxy-13,14-dihydro-15-keto-11β,16ϵ-cycloprostaglandin E_2 (PGEM-II). Authentic $PGF_{2\alpha}$, PGFM, 6-keto-$PGF_{1\alpha}$ and PGEM-II were obtained from The Upjohn Company, Kalamazoo, Mich. [5,6,8,9,11,12,14,15]-^{3}H-$PGF_{2\alpha}$ (195

Ci/mmol), 13,14-dihydro-15-keto-[5,6,8,9,11,12,14]-^{3}H-$PGF_{2\alpha}$ (157 Ci/mmol), and [5,8,9,11,12,14,15]-^{3}H-6-keto-$PGF_{1\alpha}$ (157 Ci/mmol) were purchased from Dupont (New England Nuclear Research Products, Boston, Mass.), and 13,14-dihydro-15-keto-[5,6,8,11,12,14]-^{3}H-PGE_2 was purchased from the Amersham Corp., Arlington Heights, Ill. Anti-$PGF_{2\alpha}$–bovine serum albumin serum was obtained from Dr. Leon Speroff. Anti–6-keto-$PGF_{1\alpha}$–bovine serum albumin serum was obtained from Professor G. C. Liggins, Auckland, New Zealand. Rabbit anti-PGFM and anti-PGEM-II were obtained from Dr. F. Fitzpatrick of The Upjohn Company, Kalamazoo, Mich. Validation of the PGFM and PGEM-II assays was published previously.[12] Intra-assay and interassay coefficients of variation were 7.2% and 15.8%, respectively, for the PGFM assay and 7.3% and 15.7%, respectively, for the PGEM-II assay.

$PGF_{2\alpha}$ and 6-keto-$PGF_{1\alpha}$ were measured in separate aliquots of 0.3 ml and 0.5 ml. After the amniotic fluid was divided into aliquots, approximately 1600 dpm of ^{3}H-$PGF_{2\alpha}$ or ^{3}H-6-keto-$PGF_{1\alpha}$ in 0.1 ml of assay buffer (0.1 mol/L phosphate buffer, 0.9% [wt/vol] sodium chloride, 0.1% [wt/vol] sodium azide, 0.1% [wt/vol] gelatin, pH 7.4), was added to monitor procedural losses and then acidified (pH 3.5 to 4.0, $PGF_{2\alpha}$; pH 0.3, 6-keto-$PGF_{1\alpha}$) by adding 30 μl of 1.0 mol/L formic acid. The prostaglandins were extracted with 5 ml of freshly distilled diethyl ether and centrifuged at 1200 × g at 4° C. The diethyl ether was transferred to glass 12 by 75 mm tubes and evaporated under nitrogen. The residue was redissolved in 0.35 ml of distilled absolute ethanol, and 0.2 ml of the extract was transferred to a separate 12 by 75 mm polypropylene tube for radioimmunoassay. A 0.1 ml aliquot of the same extract was counted to determine procedural losses.

After evaporating the ethanol, 0.2 ml of anti-$PGF_{2\alpha}$–bovine serum albumin or anti–6-keto-$PGF_{1\alpha}$–bovine serum albumin serum was added to the appropriate radioimmunoassay tubes and preincubated for 20 minutes at room temperature before the addition of either ^{3}H-$PGF_{2\alpha}$ or ^{3}H-6-keto-$PGF_{1\alpha}$ (20,000 dpm). A standard curve and amniotic fluid pools were run in each assay. After overnight incubation at 4° C, free and antibody-bound prostaglandins were separated with 1.0 ml of dextran-coated charcoal suspension (300 mg charcoal, 30 mg dextran T-70 in 100 ml assay buffer). The bound tritiated prostaglandins were subjected to liquid scintillation counting after the supernatants were decanted.

The linear range of the logit bound/unbound versus log dose standard curves was 10 to 1000 pg for $PGF_{1\alpha}$ and 7.8 to 1000 pg for 6-keto-$PGF_{1\alpha}$ and the sensitivity was 10 pg and 7.8 pg, respectively. Buffer blanks in each of the prostaglandin radioimmunoassays were below the sensitivity of the assay and were not subtracted.

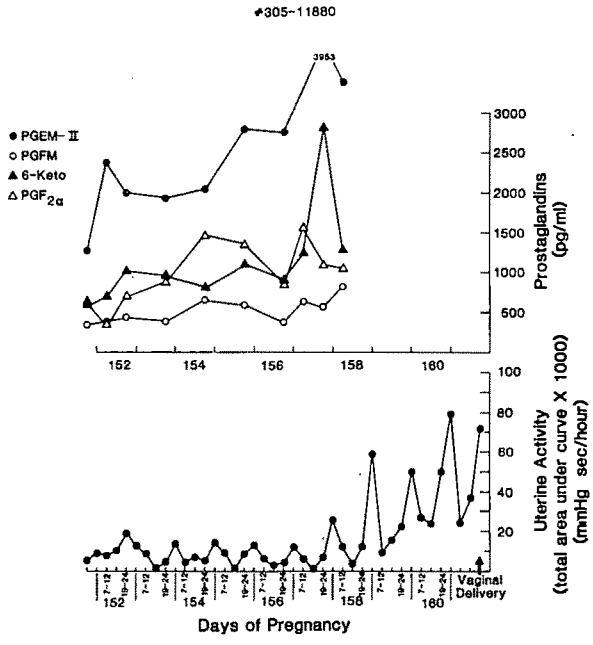

Fig. 2. Uterine activity and amniotic fluid prostaglandin concentrations in a control animal. Each point on the uterine activity scale represents the combined area under the intra-amniotic pressure contraction curve for 6-hour periods: 1:00 to 6:00 AM, 7:00 AM to 12 noon, 1:00 to 6:00 PM, and 7:00 PM to 12 midnight. The contraction area for any given hour never exceeded 20,000 mm Hg · sec/hr. The last amniotic fluid sample obtained was on day 158 of pregnancy. An increase in prostaglandin concentrations is evident before the increase in uterine activity.

Accuracy of the $PGF_{2\alpha}$ and 6-keto-$PGF_{1\alpha}$ radioimmunoassays were assessed by recovery experiments in which known amounts of each prostaglandin, ranging from 78 to 2500 pg, were added to individual 1.0 ml aliquots of amniotic fluid obtained from pregnant rhesus macaques. Linear regression analysis of the concentration measured *(y)* versus the prostaglandin concentrations added *(x)* yielded the following equations and correlation coefficients: $PGF_{2\alpha}$, $y = 1.21x + 7.9$, $r = 0.995$ (n = 4); 6-keto-$PGF_{1\alpha}$, $y = 0.94x + 57.9$, $r = 0.945$ (n = 2). Parallelism in each radioimmunoassay was tested in serially diluted aliquots of rhesus amniotic fluid spiked with the appropriate prostaglandin. In each instance, the resulting curve was parallel to the corresponding standard curve. Intra-assay and interassay coefficients of variation were 8.3% and 10.7%, respectively, for the $PGF_{2\alpha}$ radioimmunoassays and 7.7% and 13.4%, respectively, for the 6-keto-$PGF_{1\alpha}$ radioimmunoassays. PGE_2, $PGF_{1\alpha}$, PGFM, and 6-keto-$PGF_{1\alpha}$ cross reacted 1.0%, 2.91%, 0.05%, and 0.64%, respectively, with the $PGF_{2\alpha}$ antibody. PGE_2, $PGF_{2\alpha}$, and PGFM cross reacted 11.9%, 3.4%, and <0.01%, respectively, with the 6-keto-$PGF_{1\alpha}$ antibody. Cross-

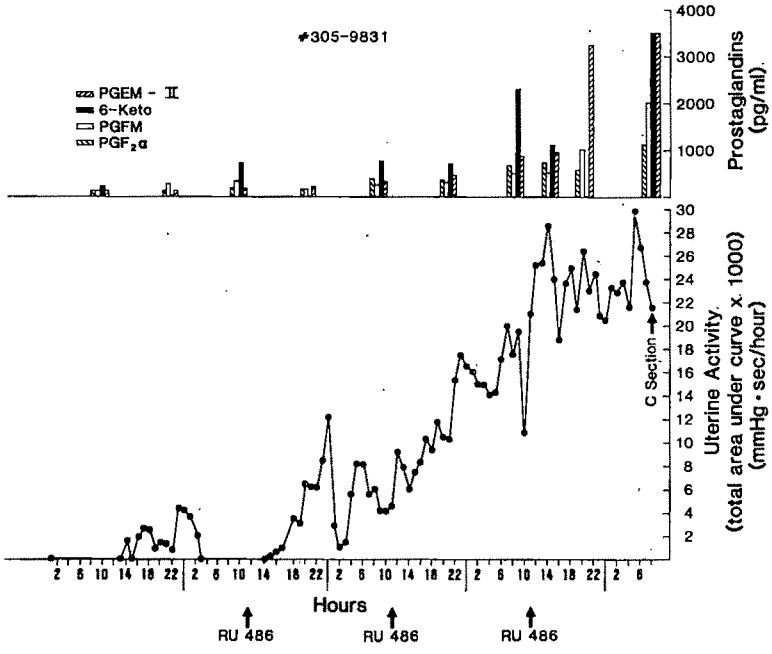

Fig. 3. Uterine activity and amniotic fluid prostaglandin concentrations in a rhesus macaque at 130 to 133 days' gestation treated with RU486 in three daily doses of 20 mg/kg/day *(arrows)*. Each point on the uterine activity graph represents the contraction area for 1 hour. Time of day is indicated on the abscissa.

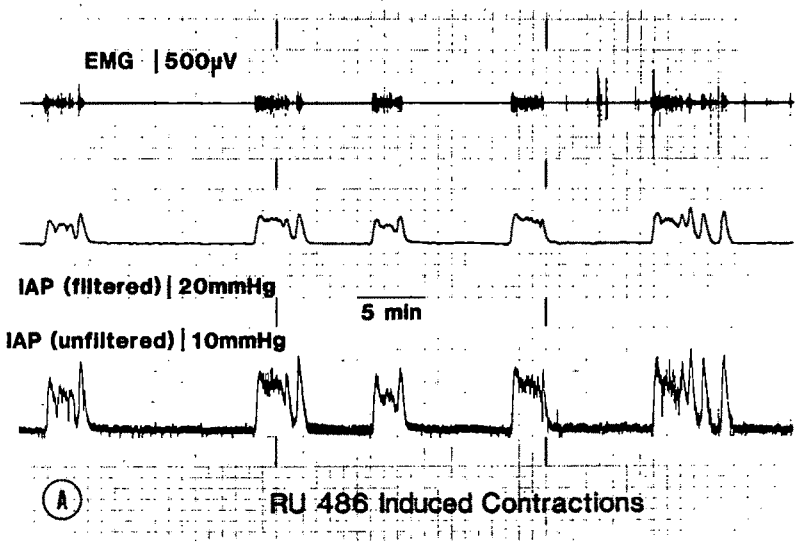
reaction was defined as $(x/y) \times 100$, where x is the mass of either $PGF_{1\alpha}$ or 6-keto-$PGF_{1\alpha}$ and y is the mass of heterologous prostaglandin at which the binding of the appropriate radioligand is reduced by 50%.



Statistics. Significant differences were determined by completely randomized one-way analysis of variance, followed by Duncan's multiple range test.

Results

Uterine activity. After an initial postsurgical increase, uterine activity (electromyogram and intra-amniotic pressure) returned to baseline levels within 48 hours after operation and remained at that level during the control period as shown 5 days after operation in Fig. 1. Electromyogram bursts occurred at a frequency of three to five per hour with minimal responses in intra-amniotic pressure. When increases in intra-amniotic pressure did occur in response to electromyogram activity, they were usually seen around midnight. Total activity did not exceed 4000 mm Hg · sec/hr and was usually <1000 mm Hg · sec/hr. All animals treated with RU486 exhibited this degree of uterine quiescence before treatment. Control animals that delivered spontaneously at term maintained a low level of uterine activity until approximately 1 week before parturition, when the nocturnal periods of activity gradually increased in intensity. These animals demonstrated a progressive increase in uterine activity beginning 2 to 3 days before vaginal delivery, with peaks in activity occurring around midnight and in the early morning hours (Fig. 2). During the 2 or 3 days before delivery, nighttime peak activity ranged between 10,000 and 30,000 mm Hg · sec/hr with lower levels of uterine activity observed during the day. In all cases, control animals demonstrated a definite diurnal variation in uterine activity, as illustrated in Fig. 2.

In contrast, animals treated with RU486 demonstrated an increase in uterine activity that reached 2000 to 12,000 mm Hg · sec/hr within 8 hours after the first dose of RU486. A transient decrease in activity occurred during the early morning hours after the first dose, which was typical for all animals, but uterine activity increased again before the second dose (Fig. 3). After the second dose of RU486, uterine activity rose progressively and reached a plateau of continuous activity at 13,000 to 30,000 mm Hg · sec/hr, which was sustained until cesarean section was performed at +72 hours. No diurnal pattern was noted.

The individual contractions occurring in animals treated with RU486 were quantitatively and qualitatively different from the contractions seen in control animals. RU486-treated animals had long-duration (3 to 7 minutes), low-frequency (five per hour), and high-amplitude (40 to 50 mm Hg) contractions that were always associated with long bursts of electromyogram activity (Fig. 4, *A*). In contrast, control animals in the final stages of labor exhibited high-frequency (about one per minute), short-duration contractions

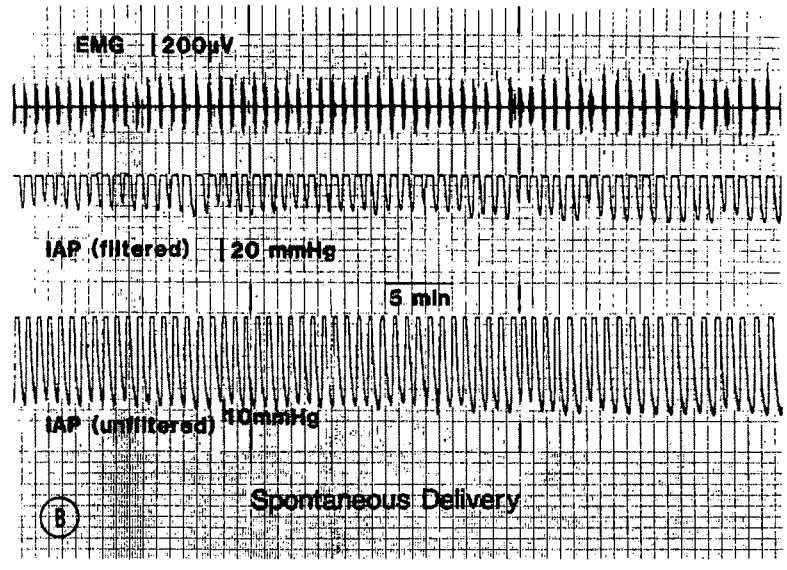


Fig. 4. Uterine activity recordings for a period of 1 hour from two different rhesus macaques demonstrating electromyogram *(EMG)* activity and corresponding intra-amniotic pressure *(IAP)* increases. *(A)* 48 hours after the beginning of RU486 treatment; *(B)* just before spontaneous delivery. The sensitivity of the electromyogram signal is 500 μV/cm in Fig. 4, *A*, and is different from that (200 μV/cm) in Figs. 1 and 4, *B*.

with an amplitude >50 mm Hg (Fig. 4, *B*). The sinusoidal waveform during active labor in control animals is similar to the nocturnal contractions seen during the last 2 to 3 days before delivery, but with lower frequency and amplitude, and were always associated with bursts of myometrial electromyogram activity.

Cervical status. The cervices of animals Nos. 9269 and 9831 changed from firm to soft within 24 hours after the first dose of RU486; a 30% effacement occurred in monkey No. 9269 at 24 hours but did not change thereafter. A 50% effacement and a 5 mm dilatation occurred in the cervix of monkey No. 9831 after 72 hours of RU486 treatment. The other two animals (Nos. 11795 and 10378) showed no change in any of the cervical parameters measured despite intense uterine activity for 72 hours. Control animals typically demonstrated progressive cervical effacement during the week before spontaneous vaginal delivery. These changes were accelerated and associated with cervical dilatation as the prepartum uterine activity intensified.

Mode of delivery and fetal status. Control animals

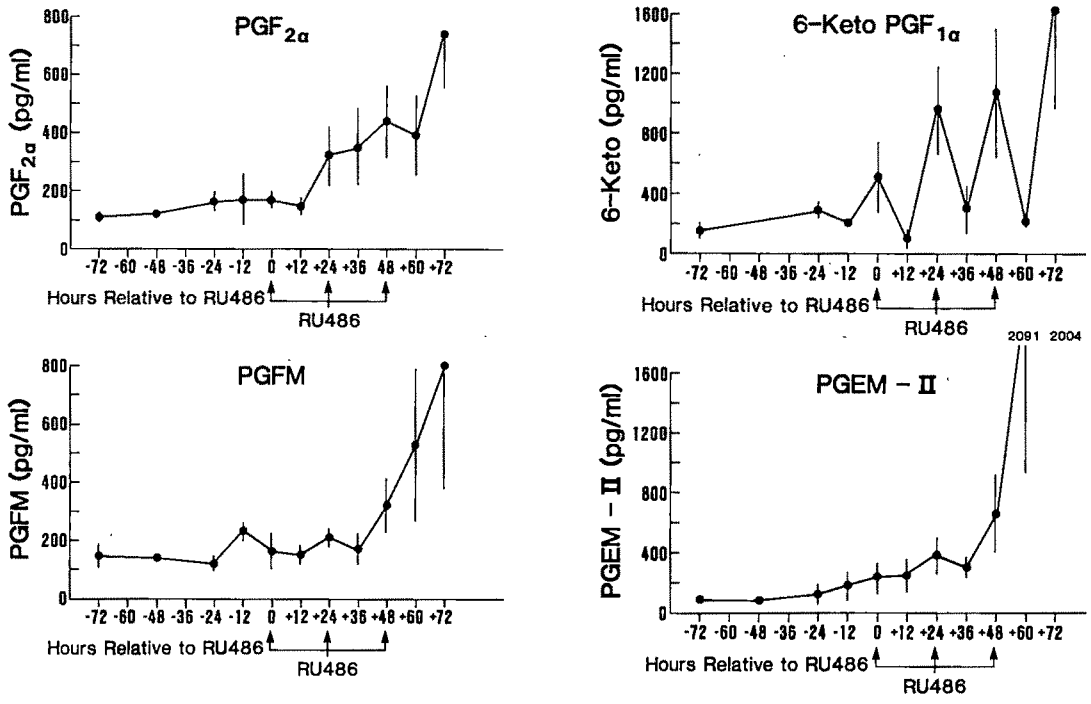

Fig. 5. Mean (±SEM) concentration of individual prostaglandins in rhesus macaques (n = 4) for 72 hours before and after RU486 administration.

were monitored for 25 to 45 days before delivery at or near term. Animal No. 11768 was delivered by cesarean section because of fetal malpresentation while in spontaneous labor with the cervix fully dilated. All other control animals delivered vaginally.

One of five RU486-treated animals underwent cesarean section 48 hours after treatment because of fetal death. At autopsy, no apparent cause of the fetal death was found, and the data for this animal were not included in the results. Repetitive and prolonged decelerations of the fetal heart rate were common in RU486-treated animals, but in spite of this, four of the five treated animals delivered live fetuses by cesarean section 72 hours after being treated with RU4886. Cesarean section was necessary because of absent cervical effacement and dilatation.

Prostaglandins. There was no apparent change in amniotic fluid prostaglandin concentrations in animals treated with RU486 until 40 hours after uterine activity began to increase or 48 hours after treatment began (Fig. 5). The first apparent change was seen in 6-keto-$PGF_{1\alpha}$ levels, which demonstrated a periodic fluctuation every 12 hours after RU486 treatment. The peak concentration of 6-keto-$PGF_{1\alpha}$ at +72 hours was significantly higher ($p < 0.05$) than previous values, except for determinations at time 0, +24 hours, and +48 hours relative to RU486 administration. The increase in amniotic fluid PGFM and PGEM-II after +48 hours did not reach statistical significance because of wide variation among animals in the concentrations of PGFM at +60 and +72 hours. Lack of an adequate amniotic fluid sample for the PGEM-II assay limited the number of data points at +60 and +72 hours. However, in the two animals for which samples were available, a nearly tenfold elevation in amniotic fluid PGEM-II was observed after RU486 treatment (300 to 400 pg/ml at +36 hours versus 2000 to 3000 pg/ml at +60 and +72 hours). The concentration of $PGF_{2\alpha}$ at +72 hours was significantly elevated ($p < 0.05$) over all values recorded earlier with the single exception of the concentration at +48 hours.

In contrast, in animals delivering spontaneously at term, amniotic fluid prostaglandins began to increase 24 to 48 hours before the rise in spontaneous uterine activity; PGEM-II increased before the other prostaglandins measured (Fig. 3). Amniotic fluid samples could not be obtained in some control animals for 24 to 72 hours before delivery because of low amniotic fluid volume or rupture of the fetal membranes. An elevation in all amniotic fluid prostaglandins was observed during the week before parturition with a significant increase in PGEM-II 3 to 6 days before birth (Table I).

Steroid hormones. The concentration of estrone and cortisol in maternal plasma did not change significantly during the experimental period for RU486-treated animals. Maternal plasma progesterone concentrations were significantly increased ($p < 0.05$) at +72 hours

Table I. Mean (±SEM) concentrations of $PGF_{2\alpha}$, PGFM, 6-keto-$PGF_{1\alpha}$, and PGEM-II at various time points before spontaneous labor and delivery in four rhesus macaques

relative to RU486 treatment. Maternal plasma estradiol concentration at +72 hours was significantly different ($p < 0.05$) only from the level at −72 hours (Table II).

Comment

This study demonstrates for the first time that progesterone receptor blockade in a primate species stimulates intense uterine activity but not the orderly sequence of changes in uterine activity profiles, amniotic fluid prostaglandins, and cervical ripening that is observed during normal parturition.

Rhesus macaques delivering spontaneously at or near term demonstrate a progressive increase in uterine activity beginning 2 to 3 days before vaginal delivery with peaks in activity occurring near midnight. Similar peaks in uterine activity have been described in rhesus macaques delivering prematurely at 130 to 155 days' gestation.[8] Spontaneous prepartum uterine contractions in rhesus macaques are characteristically of high frequency, of short duration, and of high amplitude during periods of peak activity. They are associated with progressive cervical effacement and dilatation. Three very important components are missing after RU486 administration, in contrast to the spontaneous onset of labor: (1) a diurnal pattern in myometrial activity, (2) the transition from long electromyogram events to shorter electrical bursts with sinusoidal contractions, and (3) increased cervical effacement and dilatation.

The RU486-treated animals demonstrated an increase in uterine activity within 8 hours after oral administration followed by a plateau of intense uterine activity with no diurnal variation (Fig. 3). A comparison of Figs. 1 and 4 indicates that the electrical events associated with RU486-induced activity are similar in duration and amplitude to electromyogram events in the quiescent uterus, but an increase in the number of individual potentials within electromyogram bursts after RU486 treatment is associated with a striking increase in intra-amniotic fluid pressure. This may indicate greater coupling between myometrial smooth muscle cells, but it is not clear why the RU486-induced contractions are different from the contractions observed during spontaneous labor.

In spite of sustained high levels of uterine activity for 3 days, the cervices of treated animals showed little effacement or dilatation, and cesarean section was necessary to deliver viable fetuses. It appears that blockade of the progesterone receptors alone is not sufficient to effect cervical compliance. The late response in amniotic fluid prostaglandins with absent cervical changes in RU486-treated monkeys (as compared with the prelabor increase in prostaglandins and cervical softening in spontaneous parturition) suggests that prostaglandins mediate cervical ripening and that an orderly sequence is necessary for effective labor. This is supported by data demonstrating that prostaglandin gels applied to the cervix enhance Bishop scores and improve the outcome of induced labor.[13] Relaxin, which is implicated in cervical softening, may also be deficient.

In a single previous study of RU486 administration

in nonhuman primates, cynomolgus monkeys received RU486 (20 mg/kg/day) for 3 days at various stages of gestation.[4] Abortion occurred in two of three animals treated at 30 to 40 days' gestation. Six monkeys received RU486 between days 130 and 155 of gestation; four of the six animals were primed with 10 mg/day of estradiol benzoate. Two monkeys were reportedly unaffected by the treatment, but uterine activity was not monitored. One monkey delivered a dead fetus at 171 days' gestation. The remaining three animals delivered dead fetuses within 4 to 10 days after the onset of RU486 treatment. Obstructed labor was noted in all three monkeys and cesarean section was performed in two. Our experience suggests that the obstetric difficulties described by Germain et al.[4] in cynomolgus monkeys treated with RU486 were secondary to cervical dystocia. It is of interest that by the seventh week of human gestation and more clearly thereafter, successful interruption of pregnancy by RU486 diminishes primarily because of incomplete expulsion of the conceptus.[5]

Although our study adds to the evidence that progesterone is involved in the suppression of myometrial electrical and mechanical activity during pregnancy, the mechanisms of the suppressive effect of progesterone on myometrial contractile response or on the liberation of arachidonic acid metabolites have yet to be clarified. Progesterone has a dual action on arachidonic acid metabolism to the extent that it promotes the storage of prostaglandin precursors in decidua and membranes while stabilizing lysosomes containing acylhydrolases.[14] Classical steroid receptor-acceptor action may be linked to myometrial gap junction formation[15] but not to prostaglandin production by fetal membranes since estrogen and progesterone receptors are absent in human term amnion and chorion.[16] Progesterone may act in a similar way to glucocorticoids in stimulating a 40,000 molecular weight protein (lipomodulin) that inhibits phospholipase activity.[17]

In addition, this study shows that the normal physiologic antepartum increase in prostaglandins is not solely dependent on the loss of inhibition by progesterone. This finding suggests active stimulation of prostaglandin production before parturition by other stimuli, e.g., estrogens or fetal factors. However, an endogenous stimulus to prostaglandin synthesis in the primate uterus has yet to be demonstrated conclusively. An important role for oxytocin in the triggering mechanism is suggested by rising decidual oxytocin receptors at term and by in vitro stimulation of prostaglandin production by human decidua.[18] Casey et al.[19] found that a substance in human fetal urine causes a dose-dependent increase in PGE_2 synthesis by amnion cells in monolayer culture. The demonstration that relaxin and prolactin are formed in human decidua suggests a potential regulatory role of these hormones in prostaglandin production.

Some progestomimetic activity of RU486 has been described in humans and rhesus macaques, but paradoxically this activity is lost in the presence of physiologic progesterone concentrations.[20] RU486 also possesses potent antiglucocorticoid activity as well as antiprogesterone activity. Dexamethasone is known to ablate diurnal rhythmicity and reduce uterine activity in rhesus macaques.[8] The effect seen by Ducsay et al.[8] was related to fetal adrenal suppression and reduced estrogen biosynthesis or to stimulation of lipomodulin synthesis. Theoretically the antiglucocorticoid effect of RU486 could synergize with the antiprogesterone effect in stimulating uterine activity when administered to monkeys. The reported effects of RU486 on peripheral levels of adrenocorticotropic hormone and cortisol are dose dependent and variable.[21] We observed no effect of RU486 on the cortisol and estrogen levels in maternal plasma until 72 hours after treatment (Table II). Moreover, the potential role of RU486 in stimulating uterine activity by antiglucocorticoid mechanisms is minimal on the basis of the tenfold to fiftyfold higher potency of RU486 as an antiprogestin.[22]

The availability of RU486 provides new opportunities to investigate the endocrine and paracrine mechanisms controlling the onset of parturient uterine activity and in the successful management of induced labor in late pregnancy. At the present time neither the safe dose, the optimal route of administration, nor the duration of RU486 therapy (needed to achieve a minimal risk-to-benefit ratio) has been established for labor induction. Future work may establish a basis for using RU486 as an adjunct to prostaglandins and/or relaxin for the safe induction of labor in the third trimester of pregnancy.

We acknowledge the assistance of Bruce Donaldson and Cynthia Thomas in the performance of the radioimmunoassays.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Cerebral oxidative metabolism in fetal sheep with multiple-dose ethanol infusion

Bryan Richardson, M.D., John Patrick, M.D., Jacobus Homan, B.Sc., Lesley Carmichael, B.Sc., and James Brien, Ph.D.

London, Ontario, Canada

Cerebral oxidative metabolism and cotylendonary blood flow were measured in 10 unanesthetized fetal sheep (127 to 132 days' gestation) during a control period, after the first, third, and fourth infusions of four doses of 0.5 gm of ethanol per kilogram of maternal body weight infused into the ewe during 5 hours, and 24 hours after ethanol infusion. Preductal arterial and sagittal vein blood samples were analyzed for oxygen content, blood gases, pH, and ethanol. Cerebral and cotylendonary blood flow were measured with a radioactive microsphere technique. Fetal blood gases and pH changed little with the ethanol infusions, although PaO_2 and oxygen content decreased 24 hours after ethanol infusion. Cotylendonary blood flow, which was decreased after the third and fourth ethanol infusions, did not account for these delayed hypoxemic changes. Similarly, cerebral oxidative metabolism was decreased when measured after each of the ethanol infusions, with no dose response or tolerance evident. This noted fall in fetal cerebral oxidative metabolism appears to be a direct depressant effect that was maximal at rather low fetal ethanol levels, which, if prolonged, might well affect cerebral growth and development. Recovery of cerebral metabolic function appeared complete by 24 hours. However, relative fetal hypoxemia was evident at this time, the mechanism of which remains to be determined. (AM J OBSTET GYNECOL 1987;157:1496-502.)

Key words: Ethanol, cerebral oxidative metabolism

Prominent among the defects noted in infants exposed to excessive maternal alcohol intake are abnormalities in brain growth and structural development[1] and dysfunction of the central nervous system,[2, 3] with an apparent dose-response relationship for these effects. Abnormalities in brain growth and development are also noted in the rat embryo exposed to ethanol, with mechanisms involving decreased protein synthesis and cellular hypoplasia.[4, 5]

We have previously shown that a short-term infusion of moderate amounts of ethanol to pregnant ewes (1.0 $gm \cdot kg^{-1}$ over a 1-hour period) results in alterations in the fetal state with the emergence of an intermediate-voltage electrocortical state and a decrease in fetal cerebral oxidative metabolism that is still evident 1 hour after ethanol infusion.[6] We hypothesized that if prolonged, this change in fetal state and decrease in cerebral oxidative metabolism might well affect fetal brain development and provide a mechanism whereby chronic alcohol intake contributes to growth anomalies and dysfunction of the central nervous system in infants exposed to alcohol in utero. It is not known, however, whether the decrease in fetal cerebral oxidative metabolism is a direct effect of the ethanol or caused by the change in fetal sleep state noted, since we have recently demonstrated a significant fall in cerebral oxygen consumption in the fetal lamb with a change from a low-voltage electrocortical state.[7] The ethanol dose–cerebral oxidative metabolism response relationship and time course for recovery also remain to be determined.

Therefore the purpose of the present study was to examine the effect of a multiple-dose maternal ethanol infusion on fetal cerebral oxygen consumption to determine if a dose-response relationship exists along with the time course for recovery and also to determine the extent to which behavioral state changes are involved in these effects. Because fetal hypoxia has also been proposed as a mechanism for ethanol-induced growth anomalies,[8] cotyledonary blood flow was measured in relation to noted fetal blood gas changes.

Material and methods

Surgical procedures. Studies were performed on 10 fetal sheep of mixed breed between 127 and 132 days' gestation (term 147 days). Fetuses were prepared for study at least 3 days before initiation of all experiments. The ewes were anesthetized with 1.5 to 2.0% halothane

and 50% oxygen to 50% nitrous oxide, and the uterus was exposed and opened through a lower abdominal midline incision. Polyvinyl catheters were placed in the brachiocephalic trunk via a fetal forelimb artery for sampling preductal arterial blood and in the femoral artery via a fetal hindlimb artery for sampling postductal arterial blood. A catheter was placed in the inferior vena cava via a fetal pedal vein, and the sagittal sinus was instrumented and sampled as previously reported.[9] Tracheal and amniotic fluid catheters were also placed as previously described.[9] Electrodes of stainless steel, Teflon-coated wire (Cooner, Chatsworth, California) were implanted biparietally on the dura for fetal electroencephalographic recordings, through the orbital ridge of the zygomatic bone of each eye for electroocular recordings, and over the sternum for fetal heart rate (FHR) recordings. A reference electrode was placed in the loose connective tissue overlying the occipital bone of the skull. The catheters, which contained heparinized saline solution, and wires were exteriorized through the flank of the ewe, and the abdomen was closed in layers. Polyvinyl catheters were then placed in the maternal femoral artery and vein. At the time of surgery, 1 gm of dihydrostreptomycin and 800,000 U of penicillin G were injected intramuscularly into the ewe, and after the uterus was closed, 1,000,000 U of penicillin G were injected into both the fetal hindlimb vein and the amniotic cavity. This antibiotic was continued daily for 2 to 3 days. After surgery, animals were maintained in individual cages suitable for continuous monitoring, with food and water available.

Physiologic measurements. Each fetal lamb was studied during a control period, after the first, third, and fourth of four multiple doses of ethanol infused into the ewe over 5 hours, and 24 hours after ethanol infusion. Strain-gauge manometers (Statham Model P-23 ID, Gould, Oxnard, California) and a strip-chart recorder (Model 78D, Grass Instrument, Quincy, Massachusetts) were used to record pressures in the trachea, amniotic fluid, and the brachiocephalic artery. Mean arterial blood pressure was calculated as diastolic plus 0.4 of systolic minus diastolic pressure. Electrical signals were processed with a common mode rejection preamplifier (Model 7 P511J, Grass Instrument). FHR was measured by means of a cardiotachometer (Model 7P44B). Fetal electrocortical and electroocular potentials were displayed directly on the chart recorder after passing through a passive band-pass filter, 0.3 to 30 Hz, on the preamplifier.

Continuous recordings of electrocortical, electroocular, tracheal pressure, amniotic fluid pressure, fetal arterial blood pressure, and FHR were begun 24 hours before ethanol infusion. Approximately 1 hour before ethanol infusion and during a period of high-voltage electrocortical with electroocular activity absent, radionuclide-labeled microspheres were injected into the fetal inferior vena cava for determination of regional blood flow distribution. This procedure was followed immediately by two paired blood samples, 5 minutes apart, which were drawn simultaneously from the brachiocephalic artery and the sagittal vein. Four doses of 0.5 gm ethanol per kilogram of maternal body weight were then infused into the maternal vena cava of each ewe over a 5-hour period. Each dose, as a 40% v/v solution of ethanol (Alcool, Liquor Control Board of Ontario), was administered by an infusion pump over 30 minutes, with a 1-hour interval between each dose to allow extravascular distribution of ethanol in the maternal and fetal compartments before each successive dose.[10] After the first, third, and fourth ethanol doses and again 24 hours after ethanol infusion, microsphere injections were again performed, followed by a paired blood sampling from the brachiocephalic

artery and sagittal vein. Fetal monitoring was continued throughout this time. Although the fetal state was not controlled for, in 25 of the 30 measurements after ethanol infusion and in eight of the nine measurements at 24 hours, the fetus was either in the high-voltage or an intermediate-voltage electrocortical state.

Each blood sample was analyzed for oxygen content, pH, P_{O_2}, P_{CO_2}, and ethanol. Results were averaged for the two control period samples to obtain a mean value. With each paired blood sample, approximately 1 ml of arterial blood and 1 ml of venous blood were withdrawn.

Oxygen content was determined in triplicate by means of a Lex-O_2-Con (Lexington Instruments, Waltham, Massachusetts) blood gas analyzer. Blood pH, P_{O_2}, and P_{CO_2} were analyzed on an ABL-3 blood gas analyzer with temperature corrected to 39° C (Radiometer, Copenhagen, Denmark). Blood ethanol concentration was measured by gas-liquid chromatography with the use of headspace analysis as previously described.[10]

Regional blood flow was measured with 15 μm diameter microspheres (New England Nuclear, Boston, Massachusetts, and 3M, New Brighton, Minnesota) labeled with one of five different radioisotopes (Cerium 141, chromium 51, strontium 85, niobium 95, or scandium 46) by means of methods previously published.[9] Reference samples were withdrawn from both the brachiocephalic and femoral arteries at a rate of 2.40 ml/min via a Harvard infusion withdrawal pump (Harvard Apparatus, Dover, Massachusetts). At the completion of each microsphere injection and subsequent blood sampling, estimated fetal blood loss was replaced with maternal blood.

On completion of the studies, the ewe and fetus were killed, and an autopsy was performed on the fetus to validate catheter placement. The fetal brain was weighed and dissected into the following regions: right and left cerebral hemispheres, subcortical structures (thalamus, epithalamus, hypothalamus, corpus striatum, and midbrain), cerebellum, pons, and medulla. The fetal cotyledons were dissected free of the myometrial tissue and fetal membranes were trimmed. All tissues were weighed separately and analyzed for radioactivity (Compugamma Model 1282, LkB Wallac Oy, Turku, Finland). Blood flow to these tissues was then calculated as previously described by Makowski et al.[11]

Data analysis. Results obtained from the 10 animals for control, ethanol infusion, and postethanol infusion periods are presented as grouped means ± SEM. One fetal lamb, with normal blood gases and pH during the control period, PaO_2 18.7 and pH 7.35, developed progressive metabolic acidosis after the fourth ethanol dose, with fetal demise occurring approximately 18 hours after ethanol infusion. In some experiments catheter failure prevented the completion of all studies in each fetus. Cerebral oxygen consumption values were calculated as the product of arteriovenous difference and cerebral blood flow. Cerebral blood flow only included flow to the cerebral hemispheres, since this is the region drained primarily by the sagittal sinus. Cerebral oxygen delivery was calculated as the product of arterial oxygen content and hemispheric blood flow. Cerebral fractional extraction of oxygen was calculated from the arteriovenous difference divided by arterial oxygen content. Electrocortical activity was assessed by visual analysis into periods of high voltage (100 to 200 μV), low-voltage (<50 μV), and intermediate-voltage electrocortical (50 to 100 μV). The data reported in Ta-

bles I to III were examined by analysis of variance for repeated measurements followed by the Newman-Keuls test if a significant F ratio was obtained ($p < 0.05$). Fetal breathing movements, electrooocular activity, and electrocortical activity, which were monitored continuously both before and after ethanol infusion, are reported separately,[12] as is the pharmacokinetics and pharmacodynamics of ethanol in the maternal fetal unit.[13]

Results

During the experiments ewes did not exhibit unusual agitation; however, during the multiple-dose ethanol infusions, the sheep appeared to have impairment of balance and spent a greater part of the time lying down. They returned to regular activity within 6 hours after ethanol infusion with no apparent ill effect.

Fetal cardiovascular and arterial metabolic measurements from the experimental periods are shown in Table I. The 5-hour multiple-dose ethanol infusion resulted in a stepwise increase in ethanol concentrations of fetal arterial blood to a maximum of 2.37 mg/ml after the fourth ethanol infusion. Although fetal arterial blood gases changed little during ethanol infusions, 24 hours after infusion, P_{O_2} significantly decreased ($p < 0.05$), whereas P_{CO_2} significantly increased ($p < 0.05$). No significant differences were noted in fetal hemoglobin concentration or in mean arterial blood pressure or FHR measured at the time of blood flow determinations.

Maternal arterial pH declined progressively during multiple-dose ethanol infusions from a control value of 7.44 ± 0.01 to 7.38 ± 0.01 after the fourth ethanol infusion ($p < 0.01$). Maternal arterial pH increased significantly 24 hours after infusion, 7.47 ± 0.01, when compared with control values ($p < 0.05$). These pH changes were largely metabolic in nature, since the base excess also showed a progressive decline from 0.6 ± 0.9 to −4.8 ± 0.7 mmol/L after the fourth ethanol infusion ($p < 0.01$) and then increased to 1.8 ± 0.9 mmol/L, although not significantly, when measured 24 hours after infusion. Maternal arterial P_{O_2} and P_{CO_2} changed little throughout the study when compared with control values, 101.4 ± 2.8 and 36.1 ± 0.5 mm Hg, respectively.

Cerebral oxygen delivery. Fetal arterial oxygen content, although unchanged during ethanol infusions, also significantly decreased when measured 24 hours after ethanol infusion ($p < 0.01$; Table II). Blood flow to the cerebral hemispheres was significantly decreased after both the first and third doses of ethanol ($p < 0.02$ and $p < 0.05$, respectively), and although still decreased after the fourth dose, it was not significant (Table II). The decrease in cerebral hemispheric blood flow with little change in arterial oxygen content resulted in a significant decrease in cerebral oxygen delivery after each of the ethanol infusions where measured (Table II).

Cerebral oxygen consumption. Cerebral oxygen consumption was 127 ± 9 μmol · 100 gm^{-1} · min^{-1} during the control period and decreased significantly where measured after each of the ethanol infusions (Table II), with a related fall in cerebral blood flow; the arteriovenous oxygen difference remaining little changed. Cerebral oxygen consumption returned to control values when measured 24 hours after ethanol infusion. The cerebral fractional extraction of oxygen, as a measure of the oxygen consumed as a fraction of that delivered, remained little changed throughout the study (Table II).

There was no measured consumption of ethanol by the brain, since the cerebral arteriovenous ethanol difference was negligible both with the infusions and 24 hours after infusion (Table II).

Regional blood flow. Control blood flows were determined during an episode of a high-voltage electrocortical state whereas subsequently electrocortical states were variable during blood flow determinations but again were usually of high or intermediate voltage.

Changes in blood flow to specific regions of the fetal brain are presented in Table III and Fig. 1. Regional

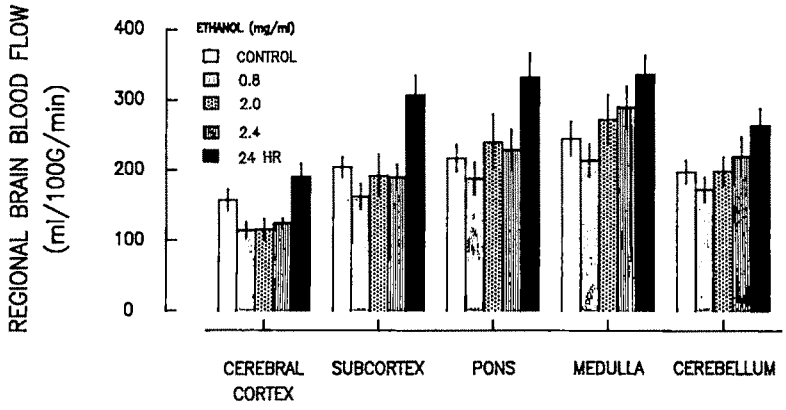

Fig. 1. Mean (± SEM) blood flows to the different brain regions during the control period, after the first, third, and fourth ethanol infusions, and 24 hours after ethanol infusion.

differences in the effect of ethanol on blood flow to the brain were evident, with flow to the cerebral hemispheres significantly decreased after both the first and third ethanol infusions (a 27% decrease), flow to the subcortical tissues significantly decreased after only the first ethanol infusion (a 20% decrease), and flow to the other brain tissues showing no significant change. Twenty-four hours after ethanol infusion, blood flow significantly increased in all regions of the brain except the cerebral hemispheres, with the increase most pronounced in the subcortex (a 50% increase) and the pons (a 53% increase).

Blood flow to the fetal cotyledons was determined during the control and ethanol infusion periods in seven of the study animals and 24 hours after ethanol infusion in five of the study animals. Cotyledonary blood flow was 193 ± 26 ml · kg^{-1} · min^{-1} during the control period and decreased significantly after both the third, 144 ± 23 ml · kg^{-1} · min^{-1} ($p < 0.01$) and the fourth, 136 ± 21 ml · kg^{-1} · min^{-1} ($p < 0.01$) ethanol infusions. Twenty-four hours after infusion, cotyledonary blood flow returned to control values, 178 ± 23 ml · kg^{-1} · min^{-1}.

Comment

The regimen of four doses of 0.5 gm ethanol per kilogram of maternal body weight administered over a 5-hour period, with each dose infused over 30-minutes, and a 1-hour interval between each successive dose, was selected in an attempt to mimic a binge-type drinking episode. This multiple-dose infusion resulted in a stepwise increase in peak fetal arterial blood ethanol concentration to 2.37 ± 0.16 mg/ml reached at the end of the fourth ethanol infusion, which is higher than that reported in other studies involving the fetal lamb.[14-17] In the present study, fetal arterial blood gases and pH changed little during the ethanol infusions; however, 24 hours later, arterial P_{O_2} significantly decreased, whereas arterial P_{CO_2} significantly increased. As noted, one fetal lamb developed progressive metabolic acidosis, with fetal death occurring approximately 18 hours after ethanol infusion. Most other studies investigating the effects of ethanol have also noted little change in fetal blood gases and pH during the ethanol infusion,[14-16] but all have involved infusions of, at most, out to 3 hours, with postinfusion measurements only out to 5 hours. The fetal blood gas changes noted here at 24 hours must involve either a decrease in oxygen delivery and carbon dioxide excretion, for example, those involving a decrease in uterine blood flow or placental exchange mechanisms or an increase in fetal oxidative metabolism and carbon dioxide production. However, these changes in fetal blood gas could not be accounted for by corresponding changes in maternal blood gas or a fall in fetal cotyledonary blood flow, which changed little from control values when measured at 24 hours.

Maternal arterial pH fell progressively during the multiple-dose ethanol infusion, which reflects a developing metabolic acidosis as indicated by the corresponding decline in the base excess. This finding has been reported in other studies in which there was lower maternal ethanol exposure[14, 15] and may represent lactic acidosis since the redox changes associated with the oxidation of ethanol result in a shift of pyruvate to lactate.[18]

Fetal cerebral uptake of oxygen decreased 22% from the control value when measured after the first maternal ethanol infusion and remained similarly depressed when measured after the third and fourth infusions despite the stepwise increase in fetal arterial ethanol levels. Thus a dose-response relationship was not evident, with cerebral oxidative metabolism maximally depressed after the first ethanol infusion. Studies in adult humans[19] support the theory that dose responsiveness may also depend on the level of consciousness, since

mild ethanol intoxication is reported to cause little change in cerebral oxidative metabolism, whereas more severe intoxication with stupor is associated with depressed cerebral oxidative metabolism. Hemmingsen and Barry[20] have also noted a significant decrease in cerebral oxygen consumption with severe ethanol intoxication in acute adult rat studies.

In a previous study during which control measurements were made in the low-voltage electrocortical state and ewes were subsequently given a 1-hour infusion of ethanol at 1.0 gm · kg^{-1} over a 1-hour period, we noted a 35% decrease in the cerebral oxidative metabolism but with an associated change to a high- or intermediate-voltage electrocortical state in most animals.[6] Because we have also reported a significant fall in cerebral oxidative metabolism in the fetal lamb with a change from a low-voltage electrocortical state to a high-voltage electrocortical state,[7] the reported decrease in cerebral oxidative metabolism may have been, at least in part, an indirect effect caused by a change in the fetal sleep state. In the present study all control metabolic measurements were made during an episode of high-voltage electrocortical potential in which rapid eye movements were absent, whereas after each of the ethanol infusions, the fetal lambs were usually either still in a high-voltage electrocortical state or in a voltage state in between that of high and low voltage. Although the significance of this intermediate-voltage state is unknown, the decrease in cerebral oxidative metabolism noted in the present study suggests a more direct effect of ethanol on cerebral metabolic function and is in keeping with abnormal brain growth and development involving decreased protein and deoxyribonucleic acid synthesis reported with ethanol exposure in other animal studies.[4, 5] The lack of a dose-response relationship noted here indicates that the direct effects of ethanol on cerebral metabolic function are maximal at rather low fetal ethanol levels, which suggests that the degree of abnormal brain growth and development reported for both the animal model[4] and human infant[1] will be a function of the duration of maternal alcohol exposure rather than the intensity of acute exposure. In the present study cerebral oxygen consumption had returned to control levels by 24 hours at a time when fetal ethanol levels were again almost negligible, indicating no discernible continued direct effects of ethanol on cerebral metabolic function.

Blood flow to the cerebral hemispheres was decreased 27% after the first and third ethanol infusions and 21% after the fourth ethanol infusion. If this decrease were caused by a direct vasoconstrictive effect of ethanol, an increase in the extraction of oxygen might be expected, since cerebral arteriovenous oxygen difference has been found to vary inversely with changes in cerebral blood flow under conditions in which cerebral oxidative metabolism remains unchanged.[21] However, with the decrease in cerebral oxidative metabolism measured in this study, the significant fall in blood flow is consistent with reports of a close coupling of regional brain blood flow to metabolic rate.[22] A direct vasoconstrictive effect of ethanol is also possible and is supported by in vitro studies on canine cerebral arterioles where local application of ethanol results in a graded constriction that can be blocked by calcium antagonists.[23] When measured 24 hours after ethanol infusion, cerebral blood flow increased above control values, although not significantly, which is in keeping with the normal regulatory response to a drop in arterial oxygen content noted at this time; the fractional oxygen extraction thus remained relatively unchanged.

Regional differences in the effect of ethanol on brain blood flow were evident, with flow to the cerebral hemispheres significantly decreased after both the first and third ethanol infusions (a 27% decrease), flow to the subcortical tissues significantly decreased after only the first ethanol infusion (a 20% decrease), and flow to the other brain tissues showing no significant change. In our previous study,[6] the fall in brain blood flow with ethanol exposure was most pronounced in the subcortex and pons, findings similar to those we have reported with a change from a low- to a high-voltage electrocortical state[7] and that further support an alteration in fetal state as an indirect mechanism whereby ethanol alters cerebral oxidative metabolism. In the present study regional blood flow changes suggest that the direct depressant effect of ethanol on oxidative metabolism is largely confined to the cerebral hemispheres, given the close coupling of blood flow to metabolism in the brain. This finding supports a decrease in protein and deoxyribonucleic acid synthesis to this area of the brain with ethanol exposure during fetal development and is consistent with reports whereby abnormalities in brain growth and function are largely confined to cortical structures.[8] Regional blood flow changes at 24 hours are again in keeping with the normal fetal response to hypoxemia whereby the greatest increase occurs to the brainstem and deep cerebral structures.[24]

Blood flow to the fetal cotyledons was decreased during the time of ethanol exposure—25% after the third infusion and 30% after the fourth infusion—with a return to control values when measured 24 hours after ethanol infusion. The control values reported here are similar to those reported by other investigators using the chronically catheterized fetal lamb preparation;[25] however we could find no reports on the effects of ethanol exposure. Erskine and Ritchie [26] have shown that the impedance of the umbilical artery was unchanged in mothers exposed to alcohol between 34 and 36 week's gestation, suggesting little effect on vascular

resistance; however, maternal alcohol levels were much less than in the present study. Because mean arterial blood pressure changed little with the ethanol infusions, the fall in cotyledonary blood flow noted here must have involved an increase in umbilical vascular resistance, presuming the central venous pressure changed little. This decrease in cotyledonary blood flow would be expected to result in a decrease in fetal oxygen delivery, and thus oxygen levels and may have contributed to the small fall in arterial oxygen content noted after the fourth ethanol infusion. The lack of a more pronounced fall in fetal arterial oxygen levels might be explained by a decrease in overall fetal metabolic rate and thus oxygen consumption with the ethanol exposure.

Thus the decrease in fetal cerebral oxidative metabolism with maternal ethanol intoxication is both a direct depressant effect, possibly involving decreased protein and deoxyribonucleic acid synthesis, and an indirect effect involving a change in fetal state. The direct depressant effect is maximal at rather low fetal ethanol levels with no dose response evident and no evidence of tolerance developing at least during the 5 hours of ethanol exposure studied. Recovery of cerebral metabolic function appears complete by 24 hours. However, relative fetal hypoxemia is now evident, the cause of which remains to be determined, but may also contribute to the growth anomalies of infants exposed to alcohol in utero.

We thank Mr. G. Smith, D. Clarke, and Dr. P. Harding for their interest in this work, and V. Ramsay for her excellent technical assistance.

Second-trimester fetal monitoring and preterm delivery in pregnancies with systemic lupus erythematosus and/or circulating anticoagulant

Maurice L. Druzin, M.D., Michael Lockshin, M.D., Terri G. Edersheim, M.D., J. M. Hutson, M.D., A. L. Krauss, M.D., and Elizabeth Kogut, R.N.C.

New York, New York

Antepartum fetal monitoring was initiated at 19 to 26 weeks' gestation in 15 pregnancies: six (five with systemic lupus erythematosus, one with circulating anticoagulant) with a complicated antepartum course (group 1); three, all systemic lupus erythematosus, with a normal antepartum course (group 2); and six normal control pregnancies (group 3). Group 1 all exhibited nonperiodic fetal heart rate decelerations, without the classical appearance of early, late, or variable decelerations, and four of the six had fetal bradycardia. In three group 1 cases, there was no active intervention because of early gestational age, and fetal death occurred at 23, 27, and 27 weeks, respectively. The other three patients in group 1 received betamethasone and were delivered by cesarean section at 28 to 30 weeks. There were no cases of respiratory distress syndrome or neonatal death. Five of the six infants in group 1 were small for gestational age. The nonperiodic fetal heart rate decelerations were absent in both groups 2 and 3 who all had normal fetal outcomes at term. The abnormal finding of women with nonperiodic fetal heart rate decelerations at 20 to 28 weeks may detect the fetus at risk for intrauterine death in pregnancies complicated by systemic lupus erythematosus or circulating anticoagulant. Continued surveillance, steroid induction of lung maturity, and delivery should be considered in these cases. (Am J Obstet Gynecol 1987;157:1503-10.)

Key words: Lupus, second trimester, nonperiodic decelerations, bradycardia, fetal death

Intrapartum electronic fetal monitoring has been shown to be reliable in the fetus who weighs ≤1500 gm.[1] Studies of antepartum fetal heart rate testing before 28 weeks' gestation have been done, but intervention in the form of delivery was often not performed because of fetal immaturity.[2-5] One parameter, fetal bradycardia during antepartum fetal heart rate testing, has been demonstrated to cause a high incidence of fetal distress in labor[6] as well as an increased incidence of antepartum fetal death and small for gestational age infants.[7, 8] The studies cited included fetuses at gestational ages of ≥32 weeks, with the exception of one patient who was evaluated at 27 weeks' gestation.[7] Current neonatal literature reports increasing survival rates of low birth weight newborn infants with a decreasing incidence of some handicaps.[9-12] These observations suggested that preterm delivery could be considered in some pregnancies with abnormal results of fetal heart rate testing.

This hypothesis can be tested with a specific high-risk group of mothers. We have previously shown that antibody to cardiolipin is a sensitive and specific indicator of fetal death and of fetal distress in pregnancies complicated by systemic lupus and/or circulating anticoagulant.[13] We now report our experience with the use of second-trimester (20 to 28 weeks) antepartum fetal heart rate testing to determine the timing of delivery in these pregnancies.

Material and methods

The duration of the study ranged from July 1980 through December 1986. Patients with systemic lupus erythematosus or circulating anticoagulant were selected for the study if they were referred for antepartum fetal heart rate testing before 26 weeks' gestation. The control patients were volunteers who agreed to undergo antepartum fetal heart rate testing starting before 26 weeks' gestation.

Fourteen patients (15 pregnancies) were evaluated by antepartum testing starting at <26 weeks' gestation. The patients were divided into three groups. Each patient's past obstetric history is detailed in Table I.

Group 1. All five patients (six pregnancies) in this

group had complicated systemic lupus erythematosus. Four of them had active systemic lupus erythematosus, defined either by abnormal serologic findings or clinical manifestations such as rash, arthritis, hypertension or renal disease. The fifth patient also had esophageal varices caused by portal vein thrombosis in infancy (Case No. 3). The fifth patient had circulating anticoagulant (Case No. 2). Four patients were taking prednisone and one was treated with aspirin alone (Case No. 5).

Group 2. Patients in this group had uncomplicated systemic lupus erythematosus and consisted of three patients with a verified diagnosis of systemic lupus erythematosus that was not active during the current pregnancy. None were taking medication.

Group 3. This group consisted of six normal volunteers with negative screening tests for systemic lupus erythematosus, circulating anticoagulant, and diabetes.

The antepartum testing scheme consisted of nonstress test as a primary screening test. A normal (reactive) nonstress test documents two or more accelerations of the fetal heart rate, each at least 15 beats/min above the baseline and associated with fetal movement, during a 20-minute monitoring period. If these criteria are not met in one of two successive 20-minute periods, the test is considered nonreactive and a contraction stress test is performed. Interpretation of the contraction stress test is made according to the criteria of Schifrin et al.[14]

Fetal bradycardia is defined as a decrease of ≥40 beats/min from the baseline heart rate or as a reduction to ≤90 beats/min lasting at least 60 seconds (Fig. 1). A nonperiodic deceleration is defined as a deceleration of at least 10 beats/min below the baseline without the classic appearance of early, late, or variable decelerations (Fig. 2). A biophysical profile was performed if the contraction stress test was contraindicated or if amniotic fluid volume was to be evaluated.[15]

All patients had routine prenatal care and underwent frequent antepartum fetal heart rate testing, ranging from once a week to almost daily. All patients in groups 1 and 2 were seen jointly by an obstetrician and a rheumatologist.

From July 1980 to August 1985, antibody to cardiolipin was determined as follows: Two hundred microliters of a solution of cardiolipin (Avanti Polar Lipids), 90 μg/ml of ethanol-chloroform, was placed in ml wells (Linbro), evaporated by air jet, and washed, after which 200 μl of a 1 : 10 dilution of test serum was added and incubated in duplicate specimens for 7 hours in a humid chamber at room temperature. The plates were then washed again. Antibody was measured by the enzyme-linked immunosorbent assay, with alkaline phosphatase–conjugated anti–polyvalent human immunoglobulin (Sigma Chemical Co., St. Louis, Mo.) incubated for 18 hours at 4° C, and developed with *p*-nitrophenyl phosphate in diethanolamine buffer. Color development was read at 405 nm in a Titertek multiscan photometer (Flow Laboratories, Meckenheim, West Germany). Replicate assays done the same day demonstrated <5% variability. All results were standardized to a single positive serum sample, with aliquots obtained in advance for this use and tested simultaneously. Arbitrarily, 100 units of reactivity corresponds to the reaction produced by 20 μl of this serum. The upper limit of normal was considered to be the mean ± 2 SEM. Values above 50 units were considered abnormal.[13]

After August 1985, the assay for antibody to car-

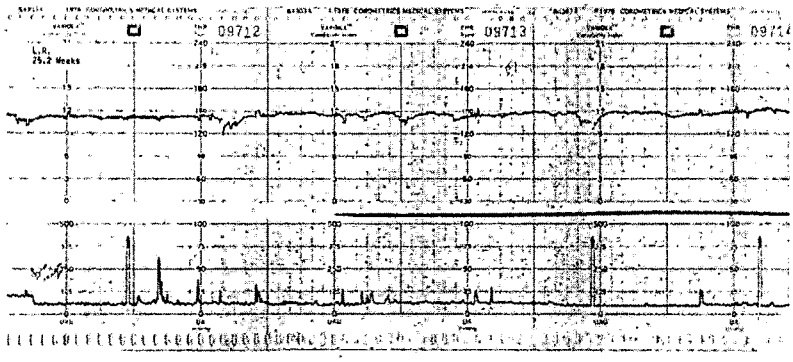

Fig. 2. Nonperiodic fetal heart rate decelerations.

diolipin was a modification of the method of Loizou et al.[16] and of the method described above, in which immunoglobulin-free fetal calf serum replaced gelatin and reagent quantities were reduced. Wells of Linbro microtiter plates were coated with 100 μl of cardiolipin, 12 μg/ml in ethanol. The plates were air dried, blocked with 10% fetal calf serum in phosphate-buffered saline. One hundred μl of serum from the patient diluted 1:100 in phosphate-buffered saline/10% fetal calf serum was added to the wells and incubated for 1 hour, then the plates were washed and developed with alkaline phosphatase–conjugated goat antihuman IgM or IgG in a standard enzyme-linked immunosorbent assay. Results were calculated as optical density at 405 nm of test well minus that of control well and normalized to a standard positive control run with each assay. Control wells containing no serum or those coated with irrelevant phospholipid uniformly gave background optical density readings of 0.18 to 0.20 in this assay. The upper limit of normal was defined as the average adjusted optical density for a normal value plus 3 SEM for 14 normal values (0.063 for IgM and 0.251 for IgG). When our previous method was compared with the new method, good correlation between the methods was obtained ($r^2 = 0.941$, $p < 0.01$).[17]

The routine clinical laboratory determined the activated partial thromboplastin time and the presence of lupus anticoagulant with citrated plasma, Actin FS activated partial thromboplastin time reagent (Dade [Becton-Dickinson], Grenoble, France), and an MFA Electra 700 Analyzer. Normal for this laboratory (mean + 4 SD) is <38 seconds. Abnormal results were confirmed at least once for each patient by mixing with normal plasma, but individual abnormal activated partial thromboplastin time results were not reconfirmed each time they occurred. The incidence of a positive lupus anticoagulant test in our obstetric population was not determined.

Amniotic fluid assessment defined oligohydramnios as the absence of at least one pocket of amniotic fluid measuring 2 by 2 cm. If only one pocket of fluid measuring 2 by 2 cm was present and no other fluid could be found, amniotic fluid volume was considered to be adequate but diminished.

Infant growth was assessed with the Brenner sea-level growth curve.[18]

In all six pregnancies from group 1, nonperiodic decelerations with or without bradycardia were noted after 20 weeks. In three cases (two with systemic lupus erythematosus and one with circulating anticoagulant) no intervention in the form of delivery was undertaken because of early gestational age and an estimated fetal

weight of <650 gm. This was done after consultation with the division of neonatology and an open discussion of the potential for survival of the fetus with the parents. Changes in medication were made, however, in two cases. In Case No. 1, prednisone was increased from 30 to 60 mg/day at 22 weeks. In Case No. 2, prednisone was gradually increased from 15 mg at 12 weeks to 30 mg from 14 to 23 weeks and up to 60 mg/day from 23 to 28 weeks. The medication was then decreased to 30 mg at 28 weeks and 20 mg at 29 weeks because of drug side effects. In the three other cases, all with systemic lupus erythematosus, betamethasone administration for induction of fetal lung maturity was instituted, and elective delivery by cesarean section was performed. Estimated fetal weight was ≥750 gm. Consultation with a neonatologist was obtained. The parents gave informed consent to the proposed plan for elective delivery.

In groups 2 and 3, pregnancy was allowed to continue in the absence of fetal and/or maternal compromise.

Results

The results are presented in Tables II and III.

Group 1. In three cases, where no intervention in the form of elective delivery was undertaken, fetal death occurred at 6, 1, and 4 days, respectively, after the last nonstress test. In the remaining three cases, betamethasone administration and delivery by cesarean

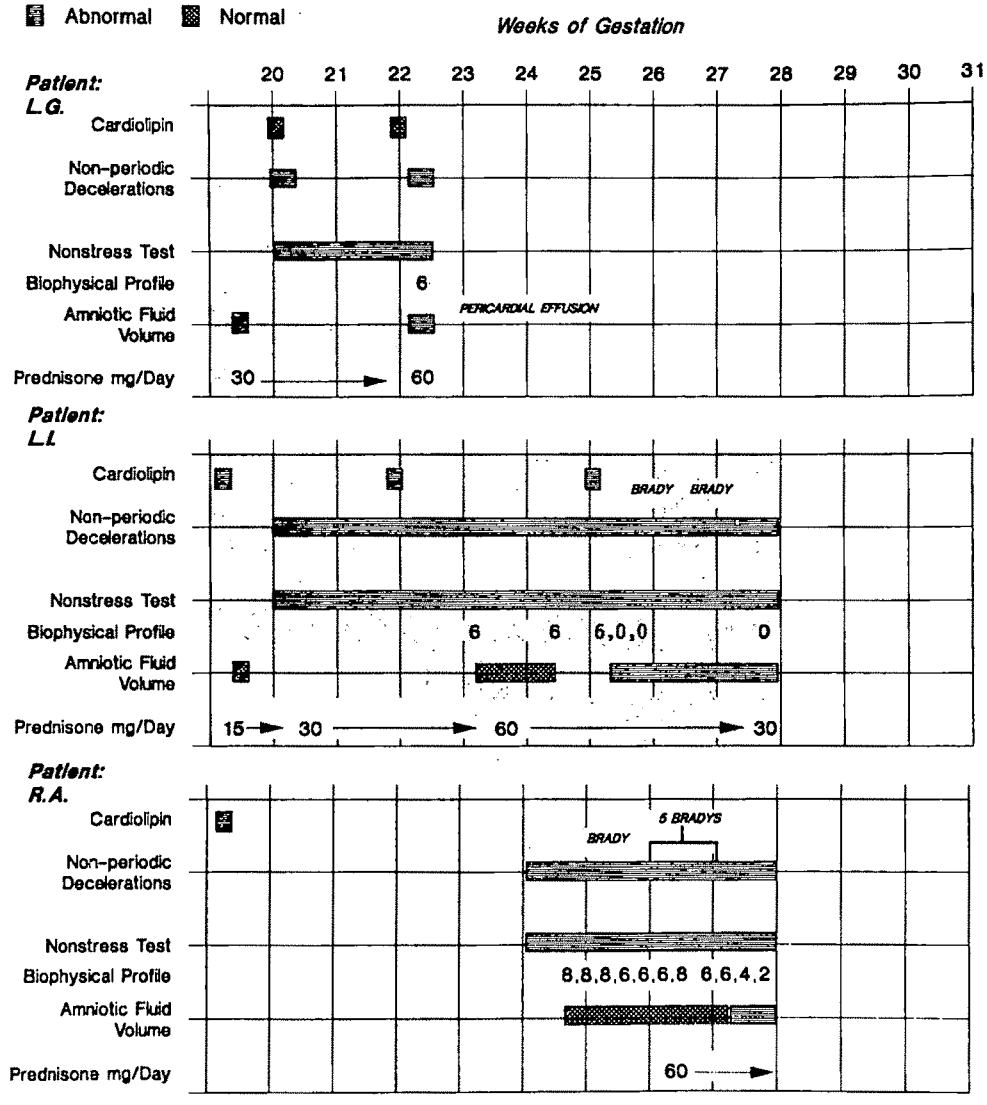

Fig. 3. Complicated lupus cases–fetal deaths.

section resulted in live births. All neonates had 1- and 5-minute Apgar scores >6.

Other indicators of fetal compromise, such as elevated antibody to cardiolipin, abnormal biophysical profile score, nonreactive nonstress tests, and decreased amniotic fluid volume, were less helpful in determining the timing of delivery (Figs. 3 and 4). The level of antibody to cardiolipin was abnormal in four out of six cases (Table IV). In all but two cases (fetal deaths, Cases Nos. 2 and 3), the biophysical profile score was ≥6 throughout the pregnancy. In the two cases of fetal death, the biophysical profile score became abnormal at 3 weeks and at 3 days, respectively, before the occurrence of fetal death. The percentage of nonreactive tests was significantly higher ($p < 0.01$) at 24 to 28 weeks' gestation in group 1 (88%) than in the other two groups (9% in group 2, 29% in group 3).

Fetal deaths. Fetal death occurred in three cases. In these three cases, sonographic evidence of oligohydramnios occurred, 2, 3, and 5 weeks, respectively, after detection of nonperiodic decelerations (Fig. 3). All three fetuses were small for gestational age. Pericardial effusion was documented on ultrasound 4 days before fetal death in Case No. 1. This patient had antibody to La antigen but not to Ro antigen. There was no evidence of congenital heart block. No unusual findings on the autopsy in the other two cases of fetal death were noted. Fetal bradycardia was the terminal pattern noted in two of the three cases of fetal death.

Live-born infants. This group consisted of three cases. Two of the three infants were small for gestational age. Oligohydramnios was noted 5 weeks after detection of nonperiodic decelerations in one case (Fig. 4) (Case No. 5). The other two cases had normal

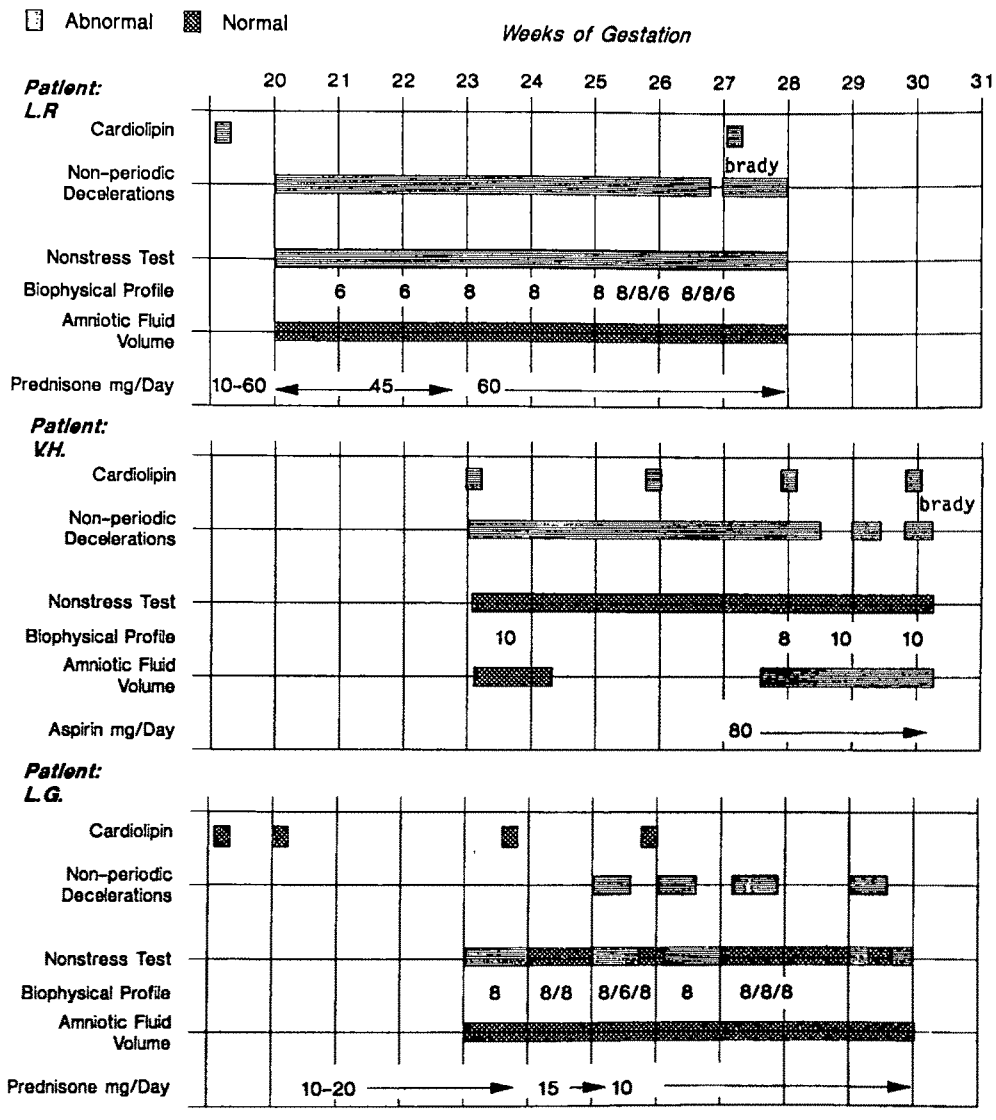

Fig. 4. Complicated lupus cases—live births.

amniotic fluid volume. Fetal bradycardia occurred in two cases and delivery took place 48 and 72 hours later (Cases Nos. 5 and 6). The mean stay in the neonatal intensive care unit for these three neonates was 85 days. Ventilator support because of respiratory distress syndrome was not required in any case.

One of the small for gestational age newborn infants (Case No. 4) developed respiratory syncytial virus pneumonia and was placed on the respirator for 3 days at 22 days of life. She was discharged after 88 days. At 26 months, this child had developed normal neurological and developmental patterns. Both height and weight were below the fifth percentile.

The second small for gestational age neonate (Case No. 5) had an uneventful course and was discharged from the hospital after 103 days. Follow-up at 4½ months revealed hypertonia, prominent primary reflexes, and increased extension. Both height and weight, corrected to 2 months, were below the third percentile.

The third neonate (Case No. 6) had necrotizing enterocolitis at 21 days of life. The infant recovered from this episode and was discharged after 64 days' stay in the intensive care unit. At 10 months of age this infant has reached normal milestones.

Group 2. No nonperiodic decelerations or bradycardias were noted in the three uncomplicated pregnancies with systemic lupus erythematosus. All pregnancies went to term and all Apgar scores were >6. However, all three patients underwent cesarean section, one because of fetal distress, one because of maternal thrombocytopenia with circulating antiplatelet antibodies,

Table IV. Laboratory data

and one because of cephalopelvic disproportion. The second infant was small for gestational age.

Group 3. All six control patients had term, uncomplicated deliveries. All Apgar scores were >6.

Comment

High levels of antibody to cardiolipin are a sensitive and specific predictor of fetal death or fetal distress. However, levels of antibody to cardiolipin cannot be used to determine the timing of elective premature delivery. The presence of nonperiodic decelerations in the second trimester may be an early indicator of fetal compromise in a select group of patients with a high risk of poor fetal outcome. These decelerations occurred long before traditional abnormal ultrasound findings such as oligohydramnios. These decelerations were noted only in the pregnancies with complicated systemic lupus erythematosus in which five of the six infants were small for gestational age. When intervention in the form of delivery was not accomplished, fetal death occurred. Fetal bradycardia was the terminal pattern in two of three cases. In the three cases in which intervention by elective delivery was accomplished, neonatal survival was 100%. Fetal bradycardia prompted delivery within 72 hours in two of three cases. In this select group of patients, the high incidence of nonreactive nonstress tests at an early gestational age did not add to the predictive reliability of the test.

In summary, nonperiodic decelerations of the fetal heart rate occurring in the second trimester in pregnancies complicated by systemic lupus erythematosus/circulating anticoagulant may be an indicator of intrauterine compromise. Bradycardia in these cases strongly suggests impending fetal death. Active intervention in terms of elective delivery may prevent fetal death. Other indicators of fetal compromise such as antibody to cardiolipin, oligohydramnios, and reactivity do not provide the obstetrician with the day-to-day information required to time an elective delivery.

We wish to acknowledge Audrey M. Waltner for her assistance in the preparation of this manuscript.

Vaginal birth after cesarean

Jeffrey P. Phelan, M.D., Steven L. Clark, M.D., Fidelia Diaz, M.A., and Richard H. Paul, M.D.

Los Angeles, California

Allowing a woman with a previous cesarean birth a trial of labor rather than performing an elective repeat cesarean section continues to be a controversial area in obstetrics today. In an effort to evaluate the risks associated with a trial of labor, a prospective investigation was undertaken from July 1, 1982, through June 30, 1984. During the first year of the study, patients with a known vertical scar or more than one prior cesarean birth were excluded from an attempted trial of labor. Beginning July 1, 1983, patients with two prior cesarean births were no longer excluded and were studied prospectively. During this 2-year period, 32,854 patients were delivered of their infants at the Los Angeles County/University of Southern California Medical Center. Of these patients, 2708 (8.2%) had undergone a prior cesarean birth, and 1796 women (66%) underwent a trial of labor. A total of 1465 (81%) of them achieved a vaginal delivery. Successful vaginal delivery by the number of prior cesarean sections was as follows: one, 82%; two, 72%; three, 90%. When contrasted with the group without a trial of labor, the group with a trial of labor had significantly less maternal morbidity. In a comparison of the groups with and without a trial of labor, the incidence of uterine dehiscence (1.9% versus 1.9%) and rupture (0.3% versus 0.5%) was similar. With the application of attempted vaginal delivery in our patients with a previous cesarean birth, we were able to reduce our cesarean delivery rate for this population alone by 54%. In summary, the benefits associated with a trial of labor in the patient with a prior cesarean birth far outweigh the risks. The policy of "once a cesarean section, always a cesarean section" should be abandoned. (Am J Obstet Gynecol 1987;157:1510-5.)

Key words: Trial of labor, cesarean delivery, uterine dehiscence

The cesarean delivery rate has continued to climb during the past decade.[1, 2] Reasons for this rise have been related to the current management of the breech presentation, the identification of fetal distress, and the management of arrest disorders during labor. Attempts to reduce the cesarean delivery rate have included external version of the breech[3] and transverse lie[4] presentations and fetal scalp[5] and acoustic[6] stimulation as an alternative to fetal scalp sampling in cases of suspected intrapartum fetal distress. While these clinical techniques are effective, their impact on reducing the cesarean section rate is small. One policy that contributed approximately 30% to this rise in cesarean birth rate is the performance of elective repeat cesarean section on the basis of a lower uterine segment scar. The National Institutes of Health Concensus Development Task Force on Cesarean Birth in 1981 suggested an evaluation of this policy to determine whether vaginal birth after cesarean section was a reasonable alternative to our traditional approach.[2]

A previous retrospective investigation from our institution demonstrated that patients with one prior cesarean birth can safely be permitted a trial of labor.[7] On the basis of this review, a prospective investigation was undertaken to determine the clinical efficacy and

safety of permitting patients with one prior cesarean section a trial of labor.[8] The purpose of this report is to augment previous observations and detail our experience in patients with two prior cesarean sections who underwent a trial of labor.

Material and methods

The study population consisted of those patients who were delivered of their infants at the Los Angeles County/University of Southern California Medical Center, which is the teaching hospital for the University of Southern California. The inclusion criteria are depicted in Table I. Before an attempted vaginal delivery, patients were informed of the risks, benefits, potential complications, and alternatives to a trial of labor after a prior cesarean section. After acceptance by the patient, each one underwent a trial of labor. If a patient refused attempted vaginal delivery, a repeat cesarean delivery was planned. Entry criteria were different for each year of the study. In the first year, the emphasis was on the safety of permitting patients with one prior cesarean birth a trial of labor, whereas the second year of the study included a trial of labor in patients with two prior cesarean births. Exclusion criteria for both study years included patients with a known classical cesarean section scar, multiple gestation, or malpresentation. On the basis of our prior experience described by Beall et al.,[9] patients with an unknown type of scar were allowed a trial of labor. Of note, patients with a low vertical uterine scar were not excluded from a trial of labor.

During labor, the fetal heart rate and uterine activity were continuously monitored with a direct fetal scalp electrode and an intrauterine pressure catheter in most instances. In each patient, blood was available, an intravenous line was established, oxytocin was administered according to The American College of Obstetricians and Gynecologists' guidelines,[10] and epidural anesthesia was induced when indicated. Routine nursing care was provided to all patients.

After delivery, a uterine exploration was done in an attempt to identify any dehiscence in those patients who achieved a vaginal delivery. For the purpose of this investigation, uterine dehiscences were subcategorized according to the need for operative intervention. Scar separations that required no intervention were termed dehiscences; those that did require intervention were termed uterine ruptures.

Data were collected from the patient's chart and logbooks while the patient remained in the hospital. Statistical evaluation was by χ^2 analysis.

Results

During the 2-year period, 32,854 patients were delivered of their infants at our institution. Of these patients, 2708 (8.2%) had undergone a prior cesarean section. Forty-one patients with an unknown intent as to a trial of labor and 24 patients with multiple gestations were excluded from the study. The remaining 2643 patients form the basis for this report.

The incidence of trial of labor for the two study years is illustrated in Table II. During this time, 170 women (8.5%) who satisfactorily met entry criteria did not desire a trial of labor and underwent a repeat cesarean section. For the study periods, the incidence of a trial of labor was 60% and 71%, respectively. A total of 1796 patients (66%) underwent a trial of labor. This represented a 15% increase during the second year that was accounted for by the threefold increase in the number of patients with two prior incisions who elected a trial

of labor. At the same time, the precentage of patients achieving a vaginal delivery was similar for both years (81%). Indications for repeat cesarean delivery after a trial of labor were: arrest disorders, 237 (72%); fetal distress, 48 (15%); and other indications, 46 (13%). During the course of labor, epidural anesthesia was induced in 244 (14%) of the patients.

Outcomes of trial of labor as they relate to previous indications are depicted in Table III. As previously demonstrated,[11] those patients with the greatest likelihood of successful vaginal delivery were those patients whose prior cesarean section indication was breech presentation. Those patients least likely to achieve a vaginal delivery were those whose previous cesarean section was done for cephalopelvic disproportion–failure to progress. While the latter group had the least success, more than 75% of these patients were delivered vaginally. Fetal distress as an indication for primary cesarean section was not found to be a recurrent cause for a repeat cesarean birth during a subsequent trial of labor.

A comparison between those patients undergoing a trial of labor with those not undergoing such a trial demonstrated some marked similarities and differences between the two groups. The risk of uterine dehiscence, while insignificantly increased in the patients with a failed trial of labor (Table IV), was similar for both the overall trial of labor and no trial of labor groups (Table V). According to standard febrile morbidity criteria, the failed trial of labor group had the greatest incidence of febrile morbidity (Table IV); and this rate of febrile morbidity was comparable to that of our primary cesarean section population. However, the overall trial of labor group had significantly less febrile morbidity (Table V) and a shorter hospital stay (Table IV).

Oxytocin administration during an attempted vaginal delivery remains controversial. Our results are illustrated in Table VI. During the second year of the study, oxytocin administration increased 26% over that of the previous year, and oxytocin was given to 793 patients (44%) undergoing a trial of labor. The indications for oxytocin use were induction of labor in 59 patients (7%) and augmentation of labor in 734 patients (93%). Irrespective of the indication for oxytocin, successful vaginal delivery was achieved in 70% of the patients who received oxytocin compared with 91% (908/1003) of patients who did not receive oxytocin. When patients who received oxytocin were contrasted with those who did not, the incidence of repeat cesarean section for fetal distress (3% for each) and the rate of uterine dehiscence (3% and 2%) were comparable. The combination of oxytocin and epidural anesthesia was used in 178 (22%) patients. This combination was associated with a cesarean delivery rate of 31%, which is comparable to that of patients who received oxytocin alone. Moreover, the incidence of uterine dehiscence was also similar.

During the second year of the investigation, the major emphasis was on permitting patients with two prior

Table VII. Outcome of trial of labor related to number of prior cesarean deliveries

No. of prior cesarean sections	1982-1983[7]					1983-1984				
		Trial of labor		Vaginal delivery			Trial of labor		Vaginal delivery	
	No.	n	%	n	%	No.	n	%	n	%
1	923	726	76	595	82	1111	911	82	753	83
2	226	23	10	16	70	260	126	49	91	72
≥3	60	2	3	2	100	62	8	13	7	88

cesarean sections a trial of labor. The number of patients with two and three cesarean births undergoing a trial of labor increased threefold (Table VII). The likelihood of successful vaginal delivery according to the number of prior cesarean sections was as follows: one, 1348/1637 (82%); two, 107/149 (72%); and three, 9/10 (90%). The rates of oxytocin administration (50%) and the use of epidural anesthesia (15%) were also similar for patients with one and two or more cesarean sections.

Maternal morbidity relating to a trial of labor is depicted in Table V. Uterine dehiscences and rupture were similar for both study groups. In cases of uterine dehiscence, the patients usually had no clinical signs or symptoms. However, if the umbilical cord prolapsed through a dehiscent lower uterine segment or a uterine rupture occurred, these events were frequently heralded by signs of fetal distress such as severe variable fetal heart rate decelerations or a prolonged fetal heart rate deceleration. Of note, maternal pain or changes in uterine tone usually were not observed. During a trial of labor, one significant uterine rupture occurred. This patient, a 32-year-old woman, gravida 4, para 1-0-2-1, with a prior cesarean section for cephalopelvic disproportion, presented in spontaneous labor with an estimated fetal weight of 3800 gm at 40 weeks' gestation. During the course of labor, she received increasing doses of oxytocin for a protracted active phase. With the cervix at 9 cm, a sudden prolonged fetal heart rate deceleration was observed and an immediate cesarean delivery was performed. A 4600 gm infant was delivered with Apgar scores of 0, 0, and 3 at 1, 5, and 10 minutes, respectively. Findings included a posterior uterine wall rupture and an intact low transverse scar. The uterine wall defect was repaired. At the time of and before the fetal heart rate deceleration, the patient was not under epidural anesthesia, and an intrauterine pressure catheter was in place. Except for the deceleration, no classic signs or symptoms of uterine rupture were present. While the maternal postpartum course was benign, the neonatal course was complicated, ultimately leading to the death of the infant. This represents the only fetal death directly attributable to a trial of labor. It is important to note that this death could have occurred in any labor and was a labor-related death rather than having to do with her risk status because of a uterine scar.

Table VIII. Indications for hysterectomy in patients with prior cesarean birth (N = 19)

Indication	Trial of labor	No trial planned
Atony	5	6
Placenta accreta	0	5
Uterine laceration	0	2
Elective	0	1

Overall, 19 hysterectomies (0.7%) were performed in the entire study group (Table VIII). Of these, five (0.3%) were performed because of uterine atony in patients who underwent a trial of labor. Of the 14 hysterectomies performed in the group without a trial of labor, six were done because of uterine atony and hemorrhage. Hysterectomy was significantly more common in the group without a trial of labor. No patient who was delivered vaginally underwent a hysterectomy.

In the study population, there was a single maternal death caused by an autopsy-confirmed postpartum pulmonary embolus ina patient who was allowed a trial of labor but who underwent a cesarean section because of fetal distress.

The perinatal outcome for the entire study population consisted of 17 fetal deaths and 23 neonatal deaths, for a perinatal mortality rate of 15/1000 births. This perinatal mortality rate is slightly less than the overall institutional rate of 18/1000. Of the 17 fetal deaths, seven were thought to be in term fetuses (≥38 weeks) and 10 in preterm fetuses (<38 weeks). The causes of the fetal deaths at term were unknown in six instances and one fetus was noted to be anomalous. In those deaths judged to be in preterm fetuses, the causes of death were: unknown, three; anomalous, two; prolapsed cord, one; abruptio placentae, one; uterine rupture, two; intrapartum death, one. With the exception of one patient with a 4350 gm infant who was delivered by repeat cesarean section because of arrest of dilatation, those patients with a fetal death were delivered

vaginally. The two fetal deaths associated with a major uterine rupture have been previously described in detail.[7]

Of the 23 neonatal deaths, eight occurred in infants who weighed <750 gm. Of the remaining 15 neonatal deaths, 11 were in infants with multiple anomalies incompatible with life. In the remaining four patients with infant birth weights in excess of 750 gm the causes of death were: respiratory distress syndrome, one; severe erythroblastosis fetalis, one; perinatal asphyxia, two. In the two cases of perinatal asphyxia, one has been previously described in association with the posterior uterine wall rupture. The second case was in a patient with an abnormal fetal heart rate pattern and an abnormal fetal scalp pH. She underwent immediate cesarean delivery and was delivered of a 3300 gm infant with Apgar scores of 1 and 1 at 1 and 5 minutes, respectively. The baby had a complicated neonatal course and died on the eleventh day of life.

In summary, 11 of the 40 perinatal deaths occurred in infants with birth weights <750 gm. Of the remaining 29 deaths, 14 occurred in anomalous infants. In the 16 other deaths, the pregnancies were judged to be term in 10 and preterm (<38 weeks) in six. Four cases of fetal death were excluded: preterm uterine rupture, two; abruptio placentae, one; and cord prolapse, one. The corrected perinatal mortality rate for the study population is 4.5/1000.

Comment

An increasing familiarity with trial of labor in the patient with a scarred uterus has led us to increase our incidence of trial of labor, in 1983 and 1984, to 71% of patients with a prior cesarean section. Overall, 65% of our patients agreed to undergo a trial of labor. This is in marked contrast to previous reports in which the incidence of acceptance was in the range of 50% to 60%.[12-14] The two factors primarily responsible for this increase have been our policy of permitting patients with an unknown type of scar and our recent policy of allowing patients with two or more prior cesarean sections a trial of labor.

Previous indication for cesarean birth bears only little relationship to the subsequent successful vaginal delivery. Our data continue to show that those patients with the greatest likelihood of vaginal delivery are those with a prior cesarean section done because of breech presentation. Additionally, more than 75% of those patients whose prior cesarean section was done because of cephalopelvic disproportion still achieved a vaginal delivery. Irrespective of the indication for prior cesarean birth, the factors associated with an enhanced probability of vaginal delivery were a prior vaginal birth[7] and an infant with a birth weight <4000 gm.[15]

On the basis of our experience in 793 patients who underwent either induction or augmentation of labor, we believe that the use of oxytocin is a reasonable consideration in the patient with a previous cesarean birth. As is the case in the patient with an unscarred uterus, the administration of oxytocic agents should be precise, by the use of infusion pumps and coupled with careful electronic monitoring of both mother and fetus. The risk of uterine dehiscence or rupture was not significantly increased in patients receiving oxytocin. However, as previously demonstrated by Horenstein and Phelan,[16] the use of oxytocin during a trial of labor is associated with a significantly greater likelihood that a cesarean birth will need to be performed. Additionally, the use of epidural anesthesia was not associated with a greater likelihood of cesarean delivery or maternal or fetal morbidity.

The overall incidence of uterine dehiscence was 2.2%, and the incidence was similar in patients undertaking a trial of labor and in those in whom no trial of labor was planned. The apparently higher rate of dehiscence diagnosed at repeat cesarean section is more likely due to the ability to directly observe the scar. After vaginal birth, transcervical examination of the scar is more difficult and less likely to detect a subtle dehiscence. Most important, the incidence of uterine dehiscence was unrelated to the use of oxytocin, epidural anesthesia, the previous indication for cesarean section, and the number of prior cesarean births. It is important to note that uterine ruptures in the current series were associated with prior fundal or classical incisions and not lower-segment incisions; as such, we would continue to recommend that patients with a known fundal or classical uterine incision not be permitted a trial of labor.

The management of patients with a uterine defect identified at vaginal delivery is somewhat controversial. However, we adhere to our prior recommendation that nonbleeding defects in the lower uterine segment and in a hemodynamically stable patient do not need to be repaired. If there is significant bleeding, if the patient's condition is unstable, or if the defect is in the upper segment, exploratory laparotomy would be warranted and repair as indicated. The question of route of delivery in a subsequent pregnancy after the observation of a dehiscence or low-segment defect after vaginal delivery remains unanswered. While one patient in the current series with a uterine "window" did undergo an uncomplicated vaginal delivery, we would recommend elective repeat cesarean delivery in these patients.

Previous investigators have suggested that patients with more than one previous uterine incision can be safely permitted a trial of labor.[17] As demonstrated in Table VII, 72% of our patients with two prior cesarean sections who underwent a trial of labor were delivered vaginally. During labor, 48% of these patients required

oxytocin for augmentation of labor. It appears that the patient who has a primary cesarean section because of cephalopelvic disproportion and subsequently has failure of a trial of labor for the same reason has the greatest likelihood of requiring a repeat cesarean section for the same indication.

Whether the patient with an unknown type of uterine scar should be permitted a trial of labor is highly controversial. A prior report by Beall et al.[9] and the current investigation would appear to support permitting these patients a trial of labor. While more detailed studies are needed to address this question, a trial of labor in the patient with an unknown type of scar would not appear unreasonable. However, before a trial of labor is undertaken in these patients, consultation with a perinatologist and informed consent from the patient should be obtained.

Traditionally, patients with a previous cesarean birth undergo an elective repeat cesarean delivery around 38 weeks' gestation. An evaluation of our perinatal mortality statistics showed that six unexplained stillbirths occurred after 38 weeks' gestation. A similar finding was also observed by Gibbs.[18] Theoretically, these fetal deaths could have been prevented by the traditional approach of elective repeat cesarean section. As a result, patients who elect to attempt vaginal delivery after cesarean section are exposed to a greater risk of fetal death, although no greater than that of a normal population at a similar gestational age, than the patient who elects a repeat cesarean birth. While more data are needed, one consideration, in an attempt to minimize the risks of fetal death while the patient awaits the onset of labor, is antepartum fetal surveillance beginning at or around 38 weeks.

A prior retrospective analysis by Boucher et al.[19] demonstrated that patients with a prior cesarean section who underwent a trial of labor had significantly less maternal morbidity. The current investigation corroborates this observation. Overall, there was a significant decrease in both febrile morbidity and emergency hysterectomy. However, a failed trial of labor was associated with an increased risk of febrile morbidity (Table IV). While one maternal death did occur in the current investigation, this was secondary to a massive pulmonary embolus and unrelated to the trial of labor.

In summary, by permitting a trial of labor in our population with a previous cesarean section, we were able to reduce our cesarean delivery rate by 54% without a significant increase in fetal or maternal morbidity. Overall, our cesarean section rate was reduced 4.5%. Oxytocin may be safely used for the usual obstetric indications as long as one adheres to The American College of Obstetricians and Gynecologists' guidelines for oxytocin usage.[10] Third, in the patient who has had a prior cesarean birth and has reached a gestational age of 38 weeks, routine fetal surveillance may be a reasonable consideration. Fourth, in patients with two prior cesarean sections, a trial of labor appears to be a reasonable alternative. Last, our data support the view that the policy of "once a cesarean section, always a cesarean section" should be abandoned.

The reliability and clinical use of a rapid phosphatidylglycerol assay in normal and diabetic pregnancies

Samy A. Saad, M.D., Hossam E. Fadel, M.D., Kamal Fahmy, M.D., George H. Nelson, M.D., Ph.D., Mouhammed Moustafa, M.D., and Harry C. Davis
Augusta, Georgia, and Banha, Egypt

Lecithin phosphorus concentration, the standard fetal lung maturity test in our institution, and phosphatidylglyercol were assayed in 69, 29, and 45 amniotic fluid samples from normal (GI), gestational (GII), and insulin-dependent diabetic (GIII) women by means of thin layer chromatography and Amniostat-FLM, respectively. Lecithin phosphorus concentration ≥0.1 mg/dl and positive or strong positive Amniostat-FLM results were considered mature. The results of both assays were concordant in 79% of the samples. The discordance rate was highest in GIII patients. In our experience, respiratory distress syndrome did not develop in neonate infants of diabetic women delivered after a mature lecithin result. With lecithin phosphorus concentration as the reference standard, the predictive value of a mature Amniostat-FLM result was 96.2%, whereas that of an immature result was 58.5%. Respiratory distress syndrome occurred in only two GIII neonates who were delivered within 72 hours of both immature lecithin and Amniostat-FLM results. These findings support the use of Amniostat-FLM as a screening test for fetal lung maturity in both normal and diabetic pregnancies. Additional tests will be necessary to evaluate further fetal lung maturity only if the results are negative. (AM J OBSTET GYNECOL 1987;157:1516-20.)

Key words: Amniostat-FLM, lecithin phosphorus concentration, fetal lung maturity, normal and diabetic pregnancies, respiratory distress syndrome

The risk of the development of respiratory distress syndrome (RDS) was reported to be higher in infants of diabetic mothers. It has been recommended that fetal lung maturity studies be performed in diabetic patients and that delivery should not be planned except after documentation of fetal lung maturity.[1] The lecithin/sphingomyelin ratio is the most widely used fetal lung maturity test.[2] At the Medical College of Georgia Hospital, the amniotic fluid concentration of lecithin, which is expressed as its phosphorus content, is measured, and a value ≥0.1 mg/dl indicates maturity in both normal and diabetic pregnancies.[1,3] Whereas several studies documented the occurrence of RDS in some infants of diabetic mothers even after attainment of "mature" lecithin/sphingomyelin ratios,[4,5] in our own experience, none of these infants delivered after the attainment of a "mature" lecithin result developed respiratory distress syndrome.[1,6]

The presence of phosphatidylglycerol in the amniotic fluid is believed to predict accurately the absence of RDS in the neonate in both normal and diabetic pregnancies.[7,8] In these studies, a thin layer chromatographic technique was used for the assay of phosphatidylglycerol. More recently, a rapid slide immunologic agglutination test has been developed for phosphatidylglycerol identification and semiquantitation and is commercially available, that is, Amniostat-FLM (Hana Biologic, Inc., Berkeley, California). The results of phosphatidylglycerol assay by thin layer chromatography and Amniostat-FLM were reported to be concordant in 90% to 95% of the cases.[9-11] The purpose of this study was to determine the degree of concordance between the results of Amniostat-FLM and our standard test (lecithin phosphorus concentration), to assess the accuracy of the former method in predicting lung maturity, and to determine its clinical use in both normal and diabetic pregnancies.

Material and methods

The study patients were managed and delivered at Medical College of Georgia Hospital from September 1983 to March 1985. Patients who had amniocentesis performed for clinical indications were recruited for this study. Twin pregnancies, as well as patients who had premature rupture of membranes or who had received glucocorticoid therapy, were excluded. Informed consent was obtained. All amniocenteses were performed with ultrasonic guidance.

The study included 122 patients divided into the following groups: 63 normal pregnant control subjects who also had a normal glucose screening test[12] (GI), 25 gestational diabetics as defined by the criteria of

O'Sullivan et al.[12] and were diet controlled (GII), and 34 insulin-dependent diabetics (GIII), made up of 21 class B, seven class C, five class D, and one class FR patients. From these patients, 143 amniotic fluid samples that were neither meconium- nor blood-stained were obtained. Sixty-nine, 29, and 45 samples were analyzed from GI, GII, and GIII patients, respectively. On receipt, one aliquot of the amniotic fluid was analyzed for the absolute concentration of lecithin as measured by its phosphorus content by means of a previously described chromatographic technique.[13] Another aliquot was analyzed for phosphatidylglycerol by Amniostat-FLM. The manufacturer's method was used, and the results were reported as either negative (no agglutination), positive (weak agglutination), or strong positive (strong agglutination). The diabetic patients were managed according to our previously published protocol.[1, 6]

The gestational age at delivery was based on menstrual dates corroborated by sonographic parameters. This did not differ from the neonatal assessment by >2 weeks in any of the study patients. The gestational age at amniocentesis was back calculated from the gestational age at delivery.

The results of both Amniostat-FLM and lecithin phosphorus concentration were recorded as mature or immature. For Amniostat-FLM, the positive and strong positive results were recorded as mature whereas the negative results were recorded as immature. Lecithin phosphorus concentration in amniotic fluid ≥0.1 mg/dl was considered mature, and concentrations <0.1 mg/dl were considered immature. With the latter as the reference standard, the sensitivity, specificity, positive, and negative predictive values of Amniostat-FLM test were calculated. These were compared among the three groups by means of χ^2 analysis. The clinical parameters and the lecithin phosphorus concentration were compared by analysis of variance. When the F test in the analysis of variance was statistically significant ($p < 0.05$), Tukey's hsd procedure was used to test pairwise comparisons posthoc.

Result

The insulin-dependent diabetic patients were slightly but significantly older than the normal group (28.9 ± 6.7 versus 24.3 ± 5.0 years). There were no significant differences in gestational age at amniocentesis (37.7 ± 2.5, 37.8 ± 1.5, 37.0 ± 2.0 weeks in GI, GII, and GIII, respectively). The range was 29 to 42 weeks in GI, 34 to 41 weeks in GII, and 30 to 40 weeks in GIII patients. The gestational age at delivery was slightly but significantly less in GIII patients than in GI and GII patients (38.0 ± 1.8 versus 39.0 ± 1.6 and 39.0 ± 1.5 weeks, respectively).

In all three groups, lecithin phosphorus concentration was significantly higher when the Amniostat-FLM

*Percentage.
†Significantly lower than in GI.

result was either positive or strongly positive than when it was negative (Table I). There were 65 samples in which Amniostat-FLM results were immature. Of those, 27 (41.5%) samples had a mature lecithin phosphorus concentration. On the other hand, in 78 samples, the Amniostat-FLM results were mature, and the lecithin phosphorus concentration was immature in only three of these (3.9%) (Table II). The results of the two tests were concordant in 113 of 143 (79%) samples. Both were immature (true immature Amniostat-FLM) in 28 (26.5%) samples, and both were mature (true mature Amniostat-FLM) in 75 (52.5%) samples (Table II). The results of the two tests were discordant in 30 of 143 (21%) samples. The discordance rate was highest (40%) in GIII samples and was significantly higher than the discordance rate (11.6%) in GI samples ($p < 0.005$). A false immature Amniostat-FLM result occurred in 27 samples, which represented 90% (27/30) of the discordant results or 18.8% (27/143) of all samples. A false mature Amniostat-FLM result occurred in only three samples, which accounted for 10% (3/30) of the discordant results or 2.1% (3/143) of all samples (Table II).

Of the 27 samples with false immature Amniostat-FLM results, seven were GI, four were GII, and 16 were GIII. The incidence of this type of discordance was significantly higher in GIII samples: 16 of 31 (51.6%) compared with seven of 48 (14.6%) in GI and four of 23 (17.4%) in GII samples ($p < 0.005$) (Table II). Delivery within 72 hours of amniocentesis occurred in three of seven GI patients, one of four GII patients, and four of 16 GIII patients; none of the neonates developed RDS. Of the three false mature Amniostat-FLM results, two were in GIII patients and one was in a GI patient; none of these neonates developed RDS. However, it should be noted that only one of these neonates (GIII) was delivered within 72 hours.

Only two infants, both GIII, developed RDS, giving an incidence of 1.6% (2/122) for the whole study and 5.9% (2/34) for GIII. Both infants were delivered within 72 hours of an immature lecithin phosphorus concentration and a negative Amniostat-FLM result.

Amniostat-FLM results were available in 91 infants delivered within 72 hours of amniocentesis. Mature results occurred in 78 infants and none developed RDS. Only two of the other 13 infants who were delivered within 72 hours of a negative Amniostat-FLM result developed RDS. None of the 101 infants who were delivered after a mature lecithin result and only two of six neonates delivered within 72 hours of an immature lecithin concentration developed RDS.

The calculated sensitivity, specificity, and predictive value of mature and immature Amniostat-FLM test results that used lecithin phosphorus concentration as the reference standard are given in Table III. The specificity and predictive value of immature results were significantly lower in GIII patients than in GI patients.

Comment

Fetal lung maturity testing has become a very important tool in the management of high-risk pregnancies, especially diabetic pregnancies. Measurement of lecithin/sphingomyelin ratio has been used extensively.[2] At the same time, measurement of the absolute lecithin concentration, expressed as its phosphorus content, was developed at our institution.[13] The incidence of false mature lecithin/sphingomyelin ratio results continued to be a problem in diabetic pregnancies, varying from 3%[4] to 27%.[5] However, using lecithin phosphorus concentration, we did not experience false mature results.[1, 6] Nevertheless, both tests share the following same disadvantages: (1) The methodology is sophisticated; (2) they need specially trained personnel; (3) they

are time-consuming; (4) they are affected by the presence of blood or meconium; (5) vaginally collected amniotic fluid samples cannot be reliably used; and (6) they are not available on a 24-hour basis in most clinical laboratories.

Certainly, the addition of phosphatidylglycerol analysis has reduced the incidence of false predictions of the absence of RDS. Moreover, phosphatidylglycerol results are reliable when amniotic fluid samples are contaminated with blood or meconium or when they are collected from vaginal pools. However, the assay of phosphatidylglycerol by means of two-dimensional thin layer chromatography[7-11, 14] is labor intensive, requires considerable technical expertise, and takes a long time (3 to 4 hours) to perform.

More recently, Amniostat-FLM was developed to determine the presence of phosphatidylglycerol in the amniotic fluid by a rapid slide immunologic agglutination method that only takes 20 to 30 minutes to perform. Garite et al.[9] found that the results of phosphatidylglycerol assayed by thin layer chromatography and the agglutination method were concordant in 91% of the samples. However, the quantities of reagents used and test conditions were slightly different from those in the Amniostat-FLM kit that we used. In two subsequent studies[10, 11] in which this kit was used, the concordance rates were 90.1% and 85%, respectively. With the lecithin/sphingomyelin ratio as the reference standard, when it was mature, Amniostat-FLM was mature in 78.4% of samples, whereas when it was <2.0, 44 of 47 (93.6%) samples were also immature by Amniostat-FLM.[10] Halverson and Gross[11] reported that of the 154 samples in which the lecithin/sphingomyelin ratio was mature, 31 samples were negative by Amniostat-FLM, whereas of the 26 samples in which the lecithin/sphingomyelin ratio was <2.0, three were positive by the Amniostat-FLM method. These results are comparable with ours. However, in two of these studies,[9, 10] there was no indication of how many diabetic patients (if any) were included. In the third study[11] there were only 11 class A and 29 insulin-dependent diabetic patients, and no attempt was made to separate the results of diabetic patients from those of the other study patients.

No previous studies compared the results of lecithin phosphorus concentration to that of phosphatidylglycerol, whether it was assayed by thin layer chromatography or by Amniostat-FLM. Using Amniostat-FLM, we found the results to be concordant in 79% of the samples. The sensitivity and specificity of Amniostat-FLM in relation to lecithin phosphorus concentration compared favorably with previously reported results that used lecithin/sphingomyelin ratio as the reference standard. The discordance rate was significantly higher in insulin-dependent diabetic patients than in the normal group, which concurs with previous reports that compared phosphatidylglycerol assayed by thin layer chromatography with lecithin/sphingomyelin ratio. Although the concordance rate in diabetic patients was about the same in these studies (56%)[8, 14] as in our (60%), the discordance rate in normal pregnant women in the present study was lower (12%) than in the other two studies—30%[14] and 40%.[8]

The incidence of RDS in our insulin-dependent diabetic patients was low (5.9%). This is the result of our management protocol, which emphasizes tight diabetic control and documentation of fetal lung maturity before planned delivery.[1, 6, 15] It also confirms the accuracy of the fetal lung maturity test we have used, that is, lecithin phosphorus concentration. We have shown that when lecithin phosphorus concentration or Amniostat-FLM was mature, RDS did not occur. On the other hand, when lecithin phosphorus concentration was <0.1 mg/dl, only two of six neonates developed RDS, and when Amniostat-FLM was immature, only two of 13 neonates developed RDS. In the previously cited studies, only eight of 21[9] and five of 19[11] neonates who were delivered within 72 hours of a negative Amniostat-FLM result developed RDS. It is clear that there were no cases of RDS in neonates delivered after a positive Amniostat-FLM result either in our study or the previous studies (total of 231 cases). It is equally clear that a negative Amniostat-FLM does not accurately predict the occurrence of RDS, a false-negative rate of 84.6% in our study, and 62%[9] and 73.7%[11] in the other studies.

Our findings indicate that Amniostat-FLM is a safe screening test for fetal lung maturity in both normal and diabetic pregnancies. For a screening test, one would prefer that which errs on the side of false immaturity so that the obstetrician does not deliver a patient based on a falsely mature value.

An additional point merits comment. In this study, four neonates were delivered within 72 hours of a mature lecithin phosphorus and negative Amniostat-FLM result, and none of these infants developed RDS. This emphasizes the point that sometimes undue delay in the delivery of a diabetic patient with a mature lecithin phosphorus concentration because of the absence of phosphatidylglycerol (as determined by a negative Amniostat-FLM) may not be warranted and may be unwise if there is suspicion or evidence of fetal compromise. This is particularly significant because our results show a higher incidence of this type of discordance in insulin-dependent diabetic patients (Table III).

In summary, we conclude that Amniostat-FLM is an accurate, simple, and rapid test of fetal lung maturity. It is safe to use as a screening test in both normal and diabetic pregnancies. It needs to be backed up by another standard test, for example, lecithin/sphingomyelin ratio or lecithin phosphorus concentration, only if the result is negative (immature), since these tests increase the predictive accuracy of the immature results. The use of a similar stepwise approach with an initial

simple screening test has also been recommended by others.[16] However, these authors used the shake test as their primary screening test, to be followed, if negative, by fluorescence polarization and then by the lecithin/sphingomyelin ratio. There was also no indication if diabetic patients were included in their study, and if so, whether the scheme was as effective in them.[16]

Correction

In the article by Blackwell and Garrison, entitled "Inhibition of prolactin secretion by antiserum to the α- and β-subunits of gonadotropin" (Am J Obstet Gynecol 1987;156:863-8), on p. 864, Table I did not contain the braces indicating a lack of significant difference. The corrected Table I appears below.

Table I. Effect of antisera to α-subunits of FSH and LH on basal and GnRH-stimulated prolactin secretion (N = 3)

Treatment	*Prolactin (ng/ml, mean ± SEM)*
Control	65 ± 7
Antiserum to α-subunit of LH	73 ± 15
Antiserum to α-subunit of FSH	39 ± 8
GnRH, 10^{-5} mol/L	160 ± 15
GnRH + antiserum to α-subunit of LH	150 ± 14
GnRH ± antiserum to α-subunit of FSH	146 ± 8

Values within each brace are not significantly different from each other.

Fetal umbilical artery flow velocimetry in postdate pregnancies

Denise A. Guidetti, M.D., Michael Y. Divon, M.D., Ralph L. Cavalieri, M.D., Oded Langer, M.D., and Irwin R. Merkatz, M.D.

Bronx, New York

This study prospectively examined the use of umbilical artery flow velocimetry for monitoring fetal health in postdate pregnancies. Forty-six patients with well-established dates were evaluated with semiweekly biophysical profiles and umbilical artery flow velocimetry (characterized by the ratio of the peak systolic to end-diastolic velocity). Their labor records were reviewed, and neonates were examined for signs of postmaturity. Twenty neonates had an abnormal test result or outcome (identified as an abnormal nonstress test, oligohydramnios, meconium, intrapartum fetal distress, or a 5-minute Apgar score <7). Nine neonates had a physical examination consistent with the postmaturity syndrome. Twenty-one neonates were entirely normal. Comparisons of the mean systolic/diastolic ratios for neonates with and without the complications associated with postdatism showed no significant differences. In addition, all systolic/diastolic ratios were within the normal range. Therefore, umbilical artery flow velocimetry is unlikely to be useful for the routine antenatal assessment of the postdate fetus. (AM J OBSTET GYNECOL 1987;157:1521-3.)

Key words: Postdates, umbilical artery velocimetry, fetal well-being

In 1951 Clifford et al.[1] reported that postmaturity of 300 days or more accounted for 30% of perinatal deaths, most of which occurred in utero. Since then, a significant decrease in perinatal deaths has been realized partly because of improvements in antepartum fetal testing. However, the increased incidence of fetal distress, the postmaturity syndrome, and meconium aspiration still contribute to neonatal morbidity. The mechanism of fetal and neonatal injury associated with the postdate pregnancy has been ascribed to progressive placental insufficiency. Histologic examination of the postdate placenta has shown an increase in the thickness of the trophoblastic basement membrane, reduction in the intervillous space caused by thrombosis with fibrin deposition, and degeneration of villi.[2]

Recently, a noninvasive evaluation of placental function has become possible by recording the umbilical artery velocity waveform by means of Doppler ultrasonography. This technique provides an indirect measure of the vascular resistance downstream from the point of measurement. An increase in the resistance to flow in the fetal villous circulation results in a decrease in the end-diastolic velocity of the umbilical artery. Various investigators have used this technique to study placental insufficiency that results in intrauterine growth retardation.[3-5] Their findings have proved useful in identifying these growth-retarded fetuses. Other investigators have advocated the application of umbilical artery flow velocimetry as a screening test to evaluate pregnancies at risk for fetal compromise.[6] The purpose of this study was to examine the ability of umbilical artery flow velocimetry to identify those fetuses at risk for adverse perinatal outcome in postdate pregnancies.

Material and methods

One hundred patients with singleton gestations were evaluated prospectively at the Maternal Fetal Assessment Center of the Albert Einstein College of Medicine beginning at 41 weeks of gestation. These patients had reliable dates, as established by last menstrual period consistent with an early clinical examination or by last menstrual period consistent with a first-trimester sonogram. Antenatal assessment of these patients was performed twice weekly until delivery and included the following: (1) umbilical artery flow velocimetry: The waveforms, obtained with the use of a continuous-wave Doppler machine (Angioscan 3, Ultrasonics, Yonkers, N.Y.), were characterized by the ratio of the peak systolic to the end-diastolic velocity. Three or more waveforms obtained during nonbreathing periods were averaged. Normal range was defined as peak systolic to end-diastolic ratio <3[7]; and (2) a biophysical profile as described by Manning et al.[8]

Forty-six of these 100 pregnancies lasted more than 294 days and had a final assessment within 4 days of delivery. Thus these patients made up the study group. Their labor records were reviewed, and the neonates were examined by one of the authors (D. G.) in con-

Table I. Peak systolic to end-diastolic ratios for normal neonates, those with signs of postmaturity, and those with abnormal test results or outcome

Group	N	Peak systolic to end-diastolic ratio		p
		Mean ± SD	Range	
Neonates with no abnormal test result, outcome, or signs of postmaturity	21	2.07 ± 0.20	1.70-2.49	
Neonates with a physical examination showing signs of postmaturity	9	2.07 ± 0.26	1.73-2.60	NS
Neonates with				
Abnormal nonstress test	7	1.95 ± 0.13	1.73-2.10	
Oligohydramnios	3	2.17 ± 0.39	1.88-2.73	
Moderate or thick meconium	13	2.03 ± 0.33	1.64-2.83	NS
Intrapartum fetal distress	4	1.97 ± 0.16	1.73-2.16	
Apgar <7 at 5 min	1	1.73 ± 0.00	—	
Neonates with one or more abnormal test result or outcome	20	2.05 ± 0.32	1.64-2.83	NS

junction with the pediatric staff for signs of postmaturity.

An abnormal test result or outcome was identified as follows: (1) an abnormal nonstress test (i.e., nonreactive or with decelerations), (2) sonographic evidence of oligohydramnios (largest pocket of fluid <2 cm in depth) confirmed at amniotomy, (3) moderate or thick meconium, (4) intrapartum fetal distress (defined as repetitive late decelerations or variable decelerations with decreased baseline variability supported by an acidotic fetal scalp pH or umbilical cord gases), and (5) Apgar score of <7 at 5 minutes.

The diagnosis of postmaturity syndrome in the neonate was made if a physical examination showed a loss of subcutaneous fat, long fingernails, and desquamation of the skin. The sample size of the study population was calculated to detect a true difference in the mean peak systolic to end-diastolic ratio of 0.20, risking only a 5% chance of failing to reject the null hypothesis of no difference. Statistical analysis was performed with the Student *t* test.

Results

The mean gestational age at delivery was 42.4 ± 0.4 (±SD) weeks (range 42 to 43.7 weeks) with a mean birth weight of 3.69 ± 0.46 kg. The cesarean section rate was 33% and no perinatal deaths occurred.

The mean peak systolic to end-diastolic ratios for those neonates who were entirely normal, those with signs of postmaturity, and those with abnormal test results or outcome are shown in Table I.

Twenty-one of 46 infants had no abnormal test result, outcome, or signs of postmaturity. Their mean peak systolic to end-diastolic ratio was 2.07 ± 0.20. Nine neonates had a physical examination showing signs of postmaturity; their mean peak systolic to end-diastolic ratio was 2.07 ± 0.26. The difference between the mean peak systolic to end-diastolic ratios of these two groups is not significant.

Seven neonates had an abnormal nonstress test, three had oligohydramnios, 13 had meconium, four had intrapartum fetal distress, and one had a 5-minute Apgar score of <7. The difference between their mean peak systolic to end-diastolic ratios and the normal group is not significant.

Twenty neonates had one or more abnormal test results or outcomes. Their mean peak systolic to end-diastolic ratio was 2.05 ± 0.32, which is also not significantly different from the normal group.

Comment

This study prospectively evaluated the usefulness of umbilical artery flow velocimetry for identifying postdate fetuses at risk. Comparisons of the peak systolic to end-diastolic ratios for neonates with and without the complications associated with postdatism showed no significant differences. All fetuses with abnormal nonstress tests, oligohydramnios, meconium, fetal distress, and the postmaturity syndrome had peak systolic to end-diastolic ratios within the normal range. Consequently, umbilical artery flow velocimetry is unlikely to be useful for routine assessment of fetal status in prolonged pregnancies. These results do not support the conclusions reached by Rightmire et al.,[9] who have recently studied 35 postdate patients and reported abnormal umbilical artery waveforms on fetuses with other than an "acceptable" outcome.

Placental insufficiency describes a process that results in impaired fetal health. The underlying pathology, however, is still poorly understood. Umbilical artery flow velocimetry has helped clarify placental insufficiency associated with intrauterine growth retardation and maternal hypertension. Trudinger et al.[5] have reported elevated peak systolic to end-diastolic ratios in

32 of 43 growth-retarded fetuses. Fleischer et al.[4] have shown that a peak systolic to end-diastolic ratio >3 had a sensitivity of 78% and a specificity of 85% in identifying the small for gestational age fetus. Giles et al.[10] were able to correlate abnormal umbilical artery waveforms with microvascular lesions in the placenta characterized by obliteration of the small muscular arteries in tertiary stem villi. Their findings help explain the increased intervillous resistance and thus the altered fetoplacental circulation found in growth-retarded fetuses.

Umbilical artery flow velocimetry is unlikely to add to the understanding of placental insufficiency associated with postmaturity. In the present study, even the most malnourished, postmature fetus had normal placental blood flow resistance, as evidenced by normal umbilical artery velocity waveforms. Other possible explanations for the underlying pathophysiology resulting in postmaturity need to be explored. There may be changes within the placenta that do not result in increased resistance to blood flow. The fetus may become less efficient in using the nutrients it receives through the placenta. It is also possible that nutrient inflow to the placenta is compromised in postmature pregnancies. From this study, we can only conclude that increased placental resistance, as reflected by abnormal umbilical artery velocity waveforms, does not seem to play a role in the pathogenesis of postmaturity.

Growth hormone, somatomedin C, and nonsuppressible insulin-like activity levels compared in premature, small, average birth weight, and large infants

Naguib A. Samaan, M.D., Ph.D., Pamela N. Schultz, R.N., B.S., Dennis A. Johnston, Ph.D., Robert W. Creasy, M.D., and Bernard Gonik, M.D.

Houston, Texas

We have investigated the relationship between growth hormone, somatomedin C, nonsuppressible insulin-like activity, weight, gestational age, and 1-minute Apgar score in newborn infants. The 153 infants were categorized as small for gestational age (n = 19), average for gestational age (n = 59), large for gestational age (n = 60), and premature (gestational age at birth, 36 weeks or less (n = 15). Our study showed that (1) growth hormone levels were elevated in premature infants and correlated with Apgar scores and birth weights; (2) somatomedin C and nonsuppressible insulin-like activity levels were significantly lower in premature than in term infants; and (3) the birth weight of all infants studied had a significant overall effect on both somatomedin C and nonsuppressible insulin-like activity levels, suggesting that these factors may be involved in fetal growth. However, because in small for gestational age infants somatomedin C and nonsuppressible insulin-like activity werre similar to levels in average for gestational age infants, it is suggested that other factors may inhibit fetal growth. (AM J OBSTET GYNECOL 1987;157:1524-8.)

Key words: Growth hormone, somatomedin C, nonsuppressible insulin-like activity, fetus

Despite the impressive progress made during the past 2 decades in understanding how hormones and growth factors regulate postnatal growth, the mechanism responsible for fetal growth in utero is poorly understood. The isolation and description of the sequence of insulin-like growth factors I and II from nonsuppressible insulin-like activity by Rinderknecht and Humbel[1] in 1976 shed some light on this important subject. Underwood and D'Ercole[2] purified and separated somatomedin C from adult human plasma and found that its structure was similar to that of insulin-like growth factor I. The isolation of growth factors I and II, also known as somatomedins, was preceded by the description of "typical" and "atypical" insulin-like activity by Samaan et al.[3] and were later called "suppressible" and "nonsuppressible" by Froesch et al.[4] Samaan et al.[5] had strong evidence that nonsuppressible or "atypical" insulin-like activity was formed after regular insulin was infused into the liver. Regular insulin ("typical insulin-like activity), or insulin extracted from the pancreas, was infused into the liver and the nonsuppressible insulin-like activity level was low in patients with liver cirrhosis and after a patient received a portocaval shunt.[6] It was also found that nonsuppressible insulin-like activity, as measured by the fat-pad assay,[7] or somatomedins, as measured by the costal-cartilage assay,[8] was low in both insulin-requiring diabetic patients and thin diabetic adults. Several investigators have considered the possibility that insulin might augment fetal growth by stimulating somatomedin production.[9, 10]

It has also been reported that growth hormone appears to be of minimal importance as a stimulator of fetal growth, since anencephaly and congenital absence of the pituitary gland are associated with normal-size infants, and fetal rabbits, rats, and monkeys that have been hypophysectomized maintain a normal rate of growth in utero.[11, 12] However, it has been shown that the growth hormone may augment the action of the insulin on the liver to form somatomedin.[13]

It has also been found that premature children have high levels of growth hormone at birth, but a correlation between the growth hormone in infants and the degree of stress (Apgar) has not been found.

We undertook this study (1) to determine the rela-

Table I. Growth hormone, somatomedin C, and nonsuppressible insulin-like activity in premature, SGA, average for gestational age, and LGA infants

Category (n)	*GH (ng/ml)*	*SMC (U/ml)*	*NSILA (μU/ml)*
Premature (15)	23 ± 11	0.46 ± 0.3	130 ± 63
SGA (19)	17.3 ± 12	0.91 ± 0.62	220 ± 102
AGA (59)	13.7 ± 8.5	0.82 ± 0.7	179 ± 113
LGA (60)	13.7 ± 12	1.1 ± 0.8	214 ± 102

AGA = Average for gestational age; GH = growth hormone; SMC = somatomedin C: NSILA = nonsuppressible insulin-like activity.

tionship between growth hormone and the degree of stress at birth as suggested by 1-minute Apgar scores and the length of gestation and (2) to compare nonsuppressible insulin-like activity, somatomedin C, and growth hormone levels in infants who were small for gestational age (SGA) with levels found in premature, large, and normal weight infants to determine the relationship of these hormones to the weight of newborn infants.

Material and methods

Umbilical cord blood was obtained in nonheparinized tubes from the placental side that contained both arterial and venous blood. The serum was separated and kept at −20° C until the time of assay. The blood was obtained from the umbilical cords of 60 large for gestational age (LGA) infants, 19 SGA infants, 59 average for gestational age infants, and 15 premature infants. Categories were based on data provided by Williams et al.[14] in a study conducted in California that used 2,288,806 livebirths. Infants who had reached 37 weeks' gestation and whose weight was in the tenth percentile or less were considered SGA. Those whose weight was in the 90th percentile or more were considered LGA, and those with weights between the 11th and 89th percentiles were considered average for gestational age. An infant was considered premature if the gestational age at birth was 36 weeks or less. The study was conducted with the approval of the Human Protection Committee of the University of Texas Health Science Center and Medical School.

Immunoreactive growth hormone was measured in 0.1 ml serum samples in duplicate by the method described by Samaan et al.[15] The addition of 1000 to 20,000 ng/ml of human placental lactogen in the assay tubes showed no cross-reaction with the growth hormone antibody used. Immunoreactive somatomedin C was measured in unextracted serum by the method of Furlanetto et al.[16] Using these immunoreactive methods, the intraassay variation was <3% and the interassay variation was <10%. The nonsuppressible "atypical" insulin-like activity was measured and transformed into units, which used the fat-pad assay, by the method of Samaan et al.[3] in quadruplicate aliquots of 0.25 ml serum. A reference serum sample (control) was included in each assay. The assay is sensitive to 4 μU insulin. The interassay and the intraassay variation coefficient of variation on different days was <10%.[3]

Table II. A summary of one-way analysis of variance for growth hormone, somatomedin C, and nonsuppressible insulin-like activity in SGA, average for gestational age, LGA, and premature neonates

	Growth hormone	*Somatomedin C*	*Nonsuppressible insulin-like activity*
F ratio	3.00	3.63	2.82
p value	<0.05	<0.05	<0.05

To make an overall comparison that tells whether there is a significant difference between the means of groups, one-way analysis of variance that uses the F test was done to determine the overall effect of birth weight on growth hormone, somatomedin C, and nonsuppressible insulin-like activity hormone levels. A multiple comparison procedure, the Tukey test, was done to locate the specific mean differences. The mean ± standard deviation and *t* test were used to compare the hormone levels between premature and term neonates. Pearson's correlation coefficient was used to analyze the correlation between hormone levels and one-minute Apgar scores. The Apgar scores recorded in the chart at the time of birth were used. The distribution of patients among groups was analyzed according to χ^2.

Results

We initially attempted to present the hormonal data by matching the infants by exact gestational age and then by analyzing the mean hormonal values to determine the relationship between weight and the values of growth hormone, somatomedin C, and nonsuppressible insulin-like activity. We believed this type of analysis was important because the distribution of subjects was significantly different with respect to premature, SGA, average for gestational age, and LGA infants. There were more LGA neonates in the 40 to 43 weeks' category than in the less than 37 weeks category ($p < 0.001$). However, too few infants were in each gestational week for gestational matching to be statistically meaningful. Therefore the data were combined as described and defined by the aforementioned method: premature, SGA, average for gestational age, and LGA.

The levels of growth hormone, somatomedin C, and nonsuppressible insulin-like activity in the SGA, pre-

Table III. Tukey test results on growth hormone, somatomedin C, and nonsuppressible insulin-like activity in premature, SGA, average for gestational age, and LGA infants

GH = Growth hormone; AGA = average for gestational age; SMC = somatomedin C; NSILA = nonsuppressible insulin-like activity.

Table IV. Mean ± SD, growth hormone, somatomedin C, and nonsuppressible insulin-like activity levels in premature and term neonates

	Growth hormone	*Somatomedin C*	*Nonsuppressible insulin-like activity*
Premature (n = 15)	23 ± 11	0.46 ± 0.34	130 ± 63
Term	14.2 ± 10.6	1.02 ± 1.0	198 ± 108
	$p < 0.001$	$p < 0.05$	$p < 0.02$

Table V. Pearson's correlation coefficient in 153 infants between growth hormone, somatomedin C, and nonsuppressible insulin-like activity levels and 1-minute Apgar scores

	Growth hormone	*Somatomedin C*	*Nonsuppressible insulin-like activity*
r value	−0.262	0.06	0.107
p value	<0.01	>0.1	>0.1

mature, average for gestational age, and LGA infants are presented in Table I. When serum growth hormone levels were subjected to one-way analysis of the variance, it was found that the infant's birth weight has an overall effect on growth hormone levels (Table II). The Tukey test was performed to locate the specific mean differences among the four groups (Table III). It was found that the growth hormone of premature infants was significantly higher than levels in LGA and average for gestational age infants ($p < 0.05$). When growth hormone levels were compared according to premature and term neonates, the growth hormone was significantly higher in premature neonates (23 ± 11 versus 14.2 ± 10.6, $p < 0.001$) (Table IV).

Somatomedin C levels were subjected to one-way analysis of variance. It was found that the birth weight of an infant has an overall effect on somatomedin C levels (Table II). According to the Tukey test, somatomedin C was significantly lower in premature infants compared with LGA infants ($p < 0.05$, Table III). When somatomedin C levels were compared in premature and term neonates, somatomedin C was significantly lower in the premature group (0.46 ± 0.34 versus 1.02 ± 1.0, $p < 0.01$) (Table IV).

When nonsuppressible insulin-like activity was subjected to one-way analysis of the variance, it was found that birth weight had an overall effect on nonsuppressible insulin-like activity levels (Table II). According to the Tukey test, nonsuppressible insulin-like activity was significantly less in premature infants compared with SGA and LGA infants ($p < 0.05$, Table III). When nonsuppressible insulin-like activity levels were compared according to premature and term neonates, premature infants had a significantly lower level of nonsuppressible insulin-like activity (130 ± 63 versus 198 ± 108, $p < 0.02$) (Table IV).

To determine if there was a correlation between growth hormone, somatomedin C, and nonsuppressible insulin-like activity levels and one-minute Apgar scores, a Pearson's correlation coefficient was calculated for all 153 infants (Table V). There was a significant negative correlation between one-minute Apgar scores and growth hormone levels in infants. There was no significant correlation between somatomedin C or nonsuppressible insulin-like activity and the one-minute Apgar score (Table V).

Comment

Various investigators have shown that growth hormone has minimal importance as a stimulator of fetal growth.[12, 13] In our studies, the growth hormone level was significantly higher in premature infants than in those of normal birth weight or in large infants, thus supporting the notion that growth hormone may not play an important part in fetal growth. We also found paradoxic relationships between the levels of growth hormone, somatomedin C, and nonsuppressible insulin-like activity in premature children compared with levels in SGA, average for gestational age, and LGA infants. Our data suggest that hormonal levels of the growth hormone, somatomedin C, and nonsuppressible insulin-like activity in neonates are a reflection of gestational age and birth weight. When term infants were categorized according to birth weight, there was an overall effect on growth hormone, somatomedin C, and nonsuppressible insulin-like activity. When these infants were compared with premature infants, there was a difference in these hormonal values. We also found that growth hormone levels correlated negatively with Apgar scores.

It has been suggested that insulin may be the main hormone responsible for intrauterine fetal growth either by its direct action or stimulation of somatomedin formation.[10, 11] This assumption was based on the observation that the administration of insulin to fetal rabbits raises plasma somatomedin activity and endogenous cartilage growth activity.[10] Similarly, Spencer et al.[11] observed that pig fetuses that were made chronically hyperinsulinemic between 90 to 104 days of gestation had significant elevations in plasma somatomedin bioactivity.

One of the early observations on somatomedins was their stimulatory effect on deoxyribonucleic acid synthesis and cell multiplication and the incorporation of inorganic sulfate into cartilage.[15, 17] These observations have been confirmed with pure insulin-like growth factor I and II.[17] It has been shown in long-term in vivo studies that insulin-like growth factor I is capable of stimulating growth indexes and body weight in the absence of growth hormone. The corresponding effect of insulin-like growth factor II is much less pronounced, and the true physiologic role of insulin-like growth factor II remains to be elucidated.[17]

We have previously shown significantly higher levels of both somatomedin C and nonsuppressible insulin-like activity in average for gestational age and LGA infants compared with premature infants,[19] but the levels of these two hormones and their relationship with the weights of SGA infants has not been studied.[18]

In the present study, we found that levels of somatomedin C and nonsuppressible insulin-like activity were affected by birth weight. However, since the levels of somatomedin C and nonsuppressible insulin-like activity were similar between the SGA and average for gestational age infants, we conclude that other factors may also be involved in inhibiting fetal growth of SGA infants. Our results also showed that growth hormone levels in neonates correlate with body weight. Growth hormone levels were highest in premature neonates and Apgar scores in this group were lowest. Although this may reflect the gestational age of the newborn infant, stress cannot be excluded from consideration.

We thank the National Pituitary Agency for supplying growth hormone and antibody for radioimmunoassay, Mr. Frank Pham and Mrs. Socorro Castillo for their technical assistance, and Ms. Barbara Reschke from the Department of Scientific Publications for editing the manuscript.

Seminal plasma proteins of fertile and infertile men analyzed by two-dimensional electrophoresis

Ramchandra R. Ayyagari, M.D., Asgerally T. Fazleabas, Ph.D., and M. Yusoff Dawood, M.D.

Chicago, Illinois

Sperm-free seminal plasma from seminal fluid ejaculate of fertile and infertile men obtained in the presence and absence of aprotinin (500 kallikrein inhibitor units per milliliter) was analyzed by two-dimensional electrophoresis followed by silver staining. To evaluate postliquefaction proteolytic breakdown of seminal plasma proteins, protease inhibitors were added to the semen at 15, 30, and 60 minutes after ejaculation. Most seminal plasma proteins in normospermic men (n = 4) had molecular weights of 30,000 to 70,000 and were similar to those present in serum. The major non–serum protein in seminal plasma of all men was a basic product with an approximate molecular weight of 40,000. A group of proteins (molecular weights = 20,000 to 23,000) in seminal plasma analyzed immediately after liquefaction was detected in oligospermic men (n = 4) but not in normospermic men (n = 4) or azoospermic men (n = 4). When protease inhibitor was added to normospermic semen at ≥15 minutes after liquefaction, these proteins (molecular weight = 20,000 to 23,000) and another group of proteins (molecular weights = 40,000 to 43,000) were readily identifiable but were further enhanced in the absence of protease inhibitors. These findings suggest that oligospermic men may have accelerated proteolysis of sperm or seminal plasma proteins that may contribute to subfertility. (AM J OBSTET GYNECOL 1987;157:1528-33.)

Key words: Seminal plasma proteins, oligospermia, azoospermia, two-dimensional electrophoresis, subfertility

Semen analysis continues to be a primary laboratory method of evaluating male fertility despite its poor predictive value except for those men with severe abnormalities. More recently, the hamster zona-free oocyte penetration test and in vitro cervical mucus penetration test have added new dimensions to the evaluation of male gametes. However, these tests also are not consistently reliable. Human seminal plasma has 18 to 55 gm protein per liter[1, 2] with 40% to 60% derived from the seminal vesicles, 35% to 40% from the prostate, and the remainder from other accessory glands. A fluid such as human seminal plasma with its complex composition and the protein contribution from the male reproductive tract is likely to have an effect on sperm survival and quality. A few limited studies have examined the electrophoretic patterns of the proteins in human seminal plasma,[3, 4] but interpretation of the data

is difficult since protease inhibitors were not added to the semen examined. Basic proteins in human seminal plasma have been shown to undergo rapid proteolysis 15 minutes after ejaculation.[5] To determine if there are differences in the protein profile of seminal plasma of fertile and subfertile men, we performed a study with two-dimensional electrophoresis to map the acidic and basic seminal plasma proteins with and without the addition of the protease inhibitor aprotinin to the semen of normal, oligospermic, and azoospermic men. This article reports the findings of our study.

Material and methods

Electrophoresis supplies. *Bis*-acrylamide and N,N,N′,N′-tetramethylethylenediamine were obtained from Biorad Laboratories, Richmond, Calif., and acrylamide was a product of Serva Biochemicals, Heidelberg, Germany; N,N′-diethyl-tartardiamide was purchased from National Diagnostics, Somerville, N.J., and ampholines were from LKB, Uppsala, Sweden. Coomassie blue R-250, sodium dodecyl sulfate, urea, dithiothreitol, protein standards, 2β-mercaptoethanol, agarose, and all other inorganic chemicals of reagent grade or better were products of Sigma Chemical Co., St. Louis, Mo. The protease inhibitor aprotinin was also purchased from Sigma Chemical Co.

Subjects and patients. Male volunteers 18 to 28 years of age were recruited from our Infertility Clinic. All subjects gave consent to provide semen samples. Normal men were defined as those who had fathered children and had two or more normal semen analyses at intervals of at least a month (sperm count >20 million/ml, >50% motility, and <40% sperm with abnormal morphologic features). Oligospermic men were those who had a history of infertility, three or more semen analyses ⩾1 month apart with a sperm count of <20 million/ml, >50% motility, and >50% sperm with normal morphologic features. Azoospermic men were those who had a history of infertility and no sperm in the ejaculate but who had fructose in the seminal plasma on at least two semen analyses ⩾1 month apart. Four normospermic, four oligospermic, and four azoospermic men were studied.

Collection of semen samples. The subjects in the study were asked to abstain from sexual activity for at least 36 hours before providing a semen sample. Ejaculates were collected by masturbation either into sterile containers without protease inhibitors or into containers that had previously been coated with 1750 kallikrein inhibitor units of aprotinin. After liquefaction, a small aliquot of each of the ejaculates was set aside for routine semen analysis. The semen samples were held at room temperature for 0, 15, 30, or 60 minutes after liquefaction. An aliquot of 250 to 500 μl (depending on the volume of the ejaculate) was removed from each ejaculate and the spermatozoa were separated from the seminal plasma by centrifugation in a microcentrifuge (10,000 g × 10 minutes). Ejaculates obtained in the absence of any aprotinin were further divided into two aliquots. One aliquot was kept at room temperature for 15, 30, or 60 minutes while aprotinin (500 kallikrein inhibitor units/ml) was added to the other at similar time intervals, then mixed in a vortex and centrifuged. The seminal plasma obtained at each time point for each treatment was separated from the sperm after centrifugation and stored at −70° C. The protein concentration in the seminal plasma obtained at each time point was determined by the method of Lowry et al.[6]

Two-dimensional polyacrylamide gel electrophoresis. Samples of seminal plasma (300 μg protein) were dissolved in 75 μl of 5 mmol/L potassium carbonate containing 9.3 mol/L urea, 2% (vol/vol) NP-40, and 0.5% (w/vol) dithiothreitol for analysis by two-dimensional polyacrylamide gel electrophoresis. The samples were analyzed by isoelectric focusing according to the method of O'Farrell[7] as modified by Horst et al.[8]

The proteins (pI < 8.0) were analyzed by isoelectric focusing in the first dimension in 4% (w/vol) acrylamide gels containing ampholines (3.5 to 10, 5 to 7, and 9 to 11, 50:35:15 by volume, respectively).

After isoelectric focusing was performed, the samples were analyzed in the second dimension by sodium dodecyl sulfate gel electrophoresis.[9] The equilibrated electrofocused gels were overlaid on 10% (w/vol) acrylamide slab gels and electrophoresis was performed toward the anode. The slabs were fixed in two changes of ethanol, acetic acid, and water (40:7:53 by volume, respectively), stained with 0.125% Coomassie blue R-250, destained, and photographed. The gels of seminal plasma proteins were then stained with silver.[10]

Results

In the seminal specimens from all male subjects studied, the major non–serum protein present in seminal plasma was a basic protein with an approximate molecular weight of 40,000. Most of the seminal plasma proteins present in normospermic men had molecular weights of 30,000 to 70,000 and were similar to those present in the serum (Fig. 1).

In oligospermic men, a group of proteins with molecular weights of 20,000 to 23,000 was present in the seminal plasma immediately after liquefaction. However, these proteins were not detected in seminal plasma of either normospermic or azoospermic men at the same time point (Fig. 1).

Fig. 2 shows the silver-stained two-dimensional electrophoretic gels of seminal plasma from normal men and the effect of proteolysis at room temperature on the appearance of the group of proteins (molecular weights 20,000 to 23,000). When the protease inhibitor

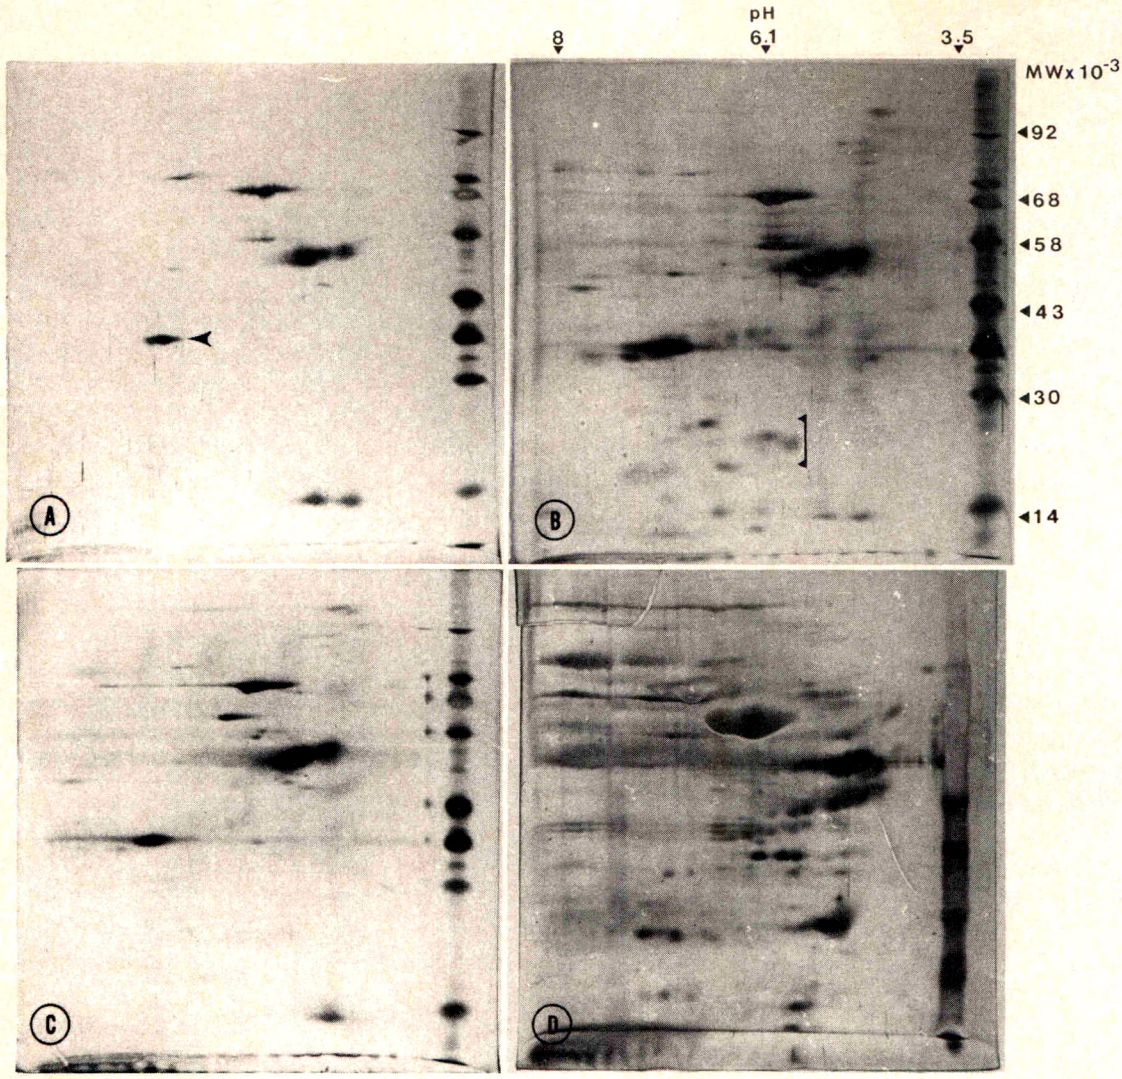

Fig. 1. Silver-stained two-dimensional electrophoretic gels of seminal plasma from normospermic *(A)*, oligospermic *(B)*, and azoospermic *(C)* men and of human plasma *(D)*. Seminal fluid ejaculates were collected in the presence of protease inhibitor. A group of proteins with molecular weights of 20,000 to 23,000 ( ) is present in seminal plasma from oligospermic men *(B)* but is absent in normospermic *(A)* and azoospermic men *(C)*. The *arrow* indicates the basic protein present in seminal plasma but not in serum.

aprotinin was not added to the ejaculate after liquefaction, the group of proteins (molecular weights 20,000 to 23,000) that was previously detected only in seminal plasma of oligospermic men (Fig. 1, *B*) appeared and increased in intensity over time. In addition, another group of proteins (molecular weights 40,000 to 43,000) also appeared in normal seminal fluid with this treatment.

When proteolysis of semen from normospermic men was inhibited by the addition of the protease inhibitor aprotinin at 15, 30, and 60 minutes after liquefaction, the two groups of proteins (molecular weights 20,000 to 23,000) that were present in normal semen after proteolysis were then also detectable by two-dimensional electrophoresis (Fig. 3). However, compared with Fig. 2, the intensity of these proteins was significantly diminished over time (Fig. 3).

Comment

Previous limited studies on seminal plasma proteins have examined only the semen of normal men.[3-5] Using two-dimensional gel electrophoresis, we found that the major non–serum protein present in the seminal plasma of both fertile and subfertile men was a basic protein with a molecular weight of 40,000. This is similar to the earlier reports of semen from normal men.[3-5]

Of greater significance, however, was our finding that

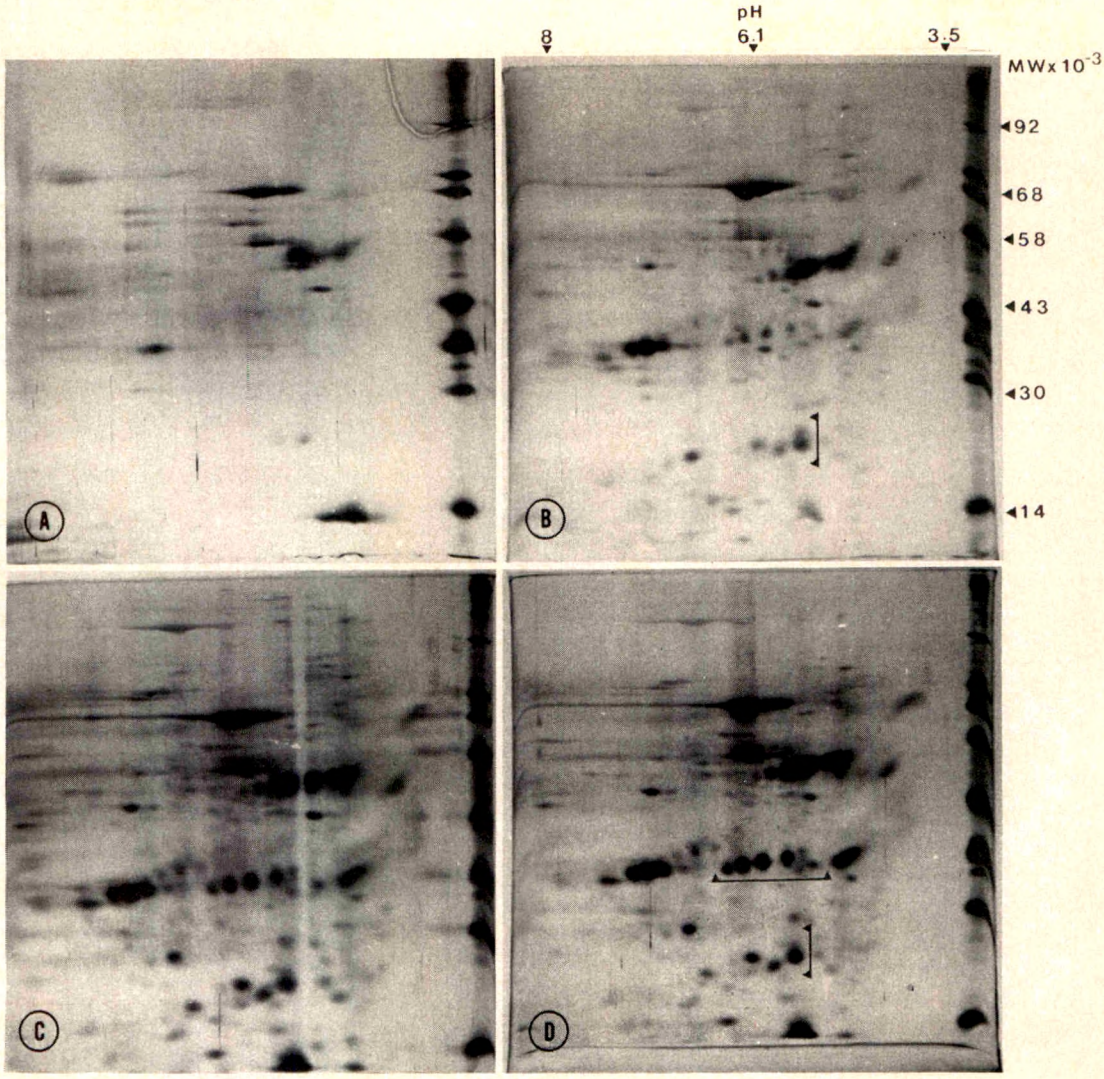

Fig. 2. Silver-stained gels after two-dimensional electrophoresis of seminal plasma from normospermic men. Ejaculates were collected in the absence of the protease inhibitor aprotinin and kept at room temperature for 0 *(A)*, 15 *(B)*, 30 *(C)*, and 60 *(D)* minutes after liquefaction. The group of proteins with molecular weights of 20,000 to 23,000 (⌈⌉) that was present in Fig. 1, *B*, appeared and increased in intensity over time after liquefaction. In addition, another group of proteins with molecular weights of 40,000 to 43,000 (▲—▲) also appeared and increased in intensity over time.

a group of proteins with molecular weights of 20,000 to 23,000 is present in the seminal plasma of oligospermic men if analysis is done immediately after liquefaction but not in the seminal plasma of normal or azoospermic men. Nevertheless, when a protease inhibitor such as aprotinin is added to normal semen 15 or more minutes after liquefaction, these proteins (molecular weights = 20,000 to 23,000) are readily identified. In addition, another group of proteins with molecular weights of 40,000 to 43,000 also became identifiable in normal seminal fluid treated with the protease inhibitor. Furthermore, the identification of these two groups of proteins (molecular weights = 20,000 to 23,000 and 40,000 to 43,000) was enhanced in the absence of protease inhibitors. Thus, a group of proteins with molecular weights of 20,000 to 23,000 is readily detected in seminal plasma immediately after ejaculation and liquefaction in oligospermic individuals. This group of proteins (molecular weights = 20,000 to 23,000) together with another group (molecular weights = 40,000 to 43,000) are detectable in the semen of normospermic individuals only when proteolytic activity is not suppressed. These proteins could not be identified in the semen of azoospermic men.

The proteins with molecular weights of 20,000 to 23,000 are most likely the products of accelerated pro-

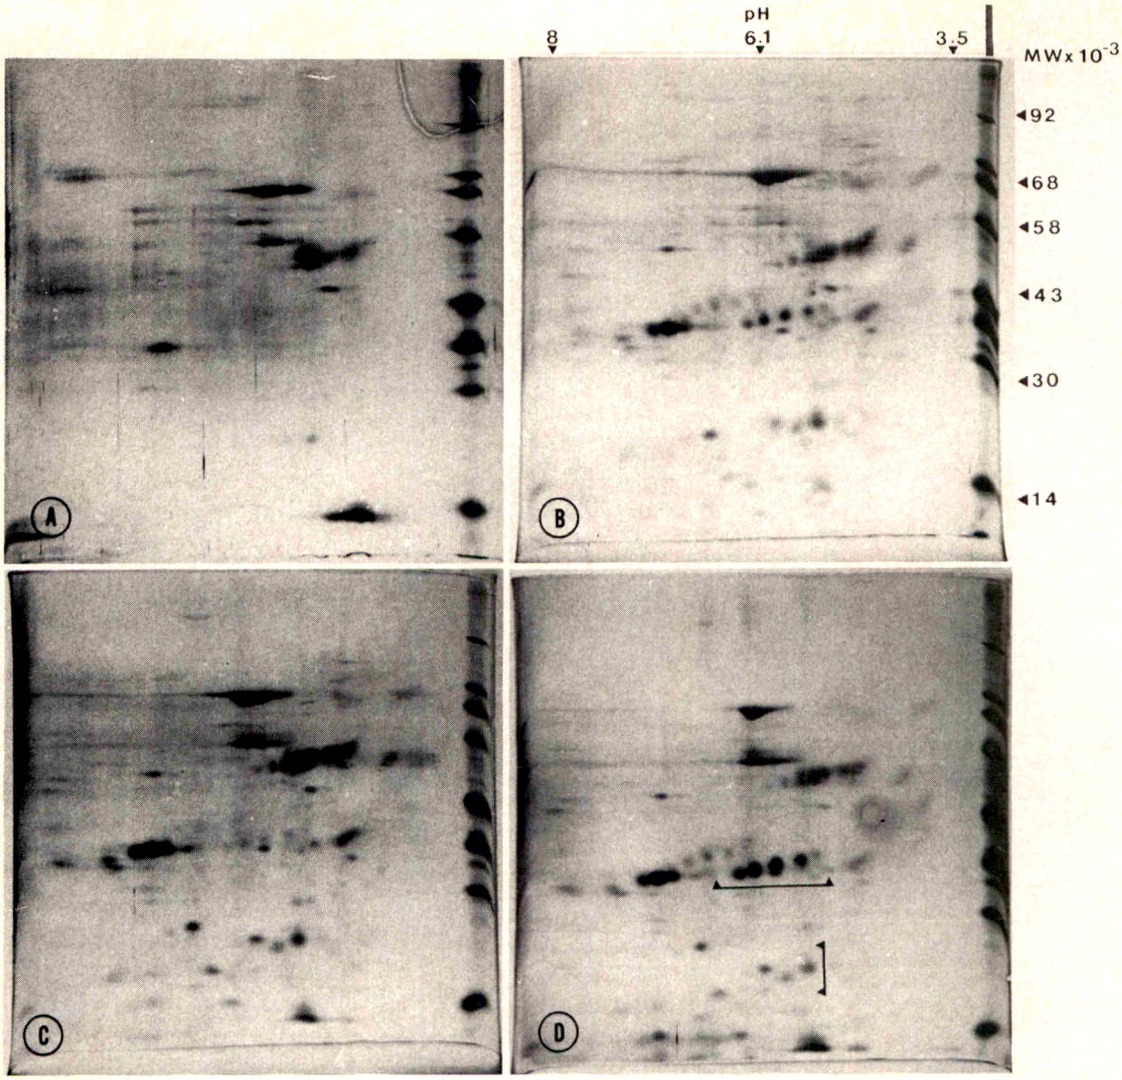

Fig. 3. Silver-stained two-dimensional electrophoretic gels of seminal plasma from normospermic men. The ejaculates were collected in the absence of the protease inhibitor aprotinin that was added at 15, 30, and 60 minutes after liquefaction. The group of proteins with molecular weights of 20,000 to 23,000 ( ) that was found in oligospermic men in Fig. 1, *B*, and under the conditions in Fig. 2 in normospermic men as well as the other group of proteins with molecular weights of 40,000 to 43,000 (▲—▲) that appeared under the conditions in Fig. 2 is now present but *diminished in intensity* over time as compared with Fig. 2.

teolysis and originate from spermatozoa that undergo proteolytic degradation. The absence of these proteins in the seminal plasma of azoospermic individuals with or without varying degrees of proteolytic inhibition suggests the spermatozoa as the source of these proteins. The rapid appearance and easy detection of these proteins in seminal plasma of oligospermic men combined with enhancement of their detection in normal seminal plasma when proteolysis is not inhibited strongly support the role of accelerated proteolysis for the generation of these proteins. Therefore, the seminal fluid of oligospermic men has apparently accelerated proteolytic activity. What is less clear, however, is whether such apparently accelerated proteolytic activity is due to increased levels of proteolytic enzyme(s) activity and/or increased susceptibility of spermatozoa to proteolytic degradation in the semen of oligospermic men. Our hypothesis and explanation can and should be further explored in investigations on previously fertile men who have undergone vasectomy, but this was not within the original scope of this study.

While previous studies have examined seminal plasma from normal men and as many as 200 protein bands were found on the two-dimensional electropho-

resis,[3-5] similar analyses have not been reported for oligospermic and azoospermic men. Nonetheless, interpretation of the data from these studies[3-5] was complicated by the fact that protease inhibitors were not added to the semen collected. The basic proteins in seminal plasma undergo rapid proteolysis 15 or more minutes after ejaculation.[5] Our findings show that proteins of 20,000 to 23,000, which are products of accelerated proteolysis in oligospermic men, also appear in normospermic seminal plasma, at a slower but normal rate of proteolysis. Furthermore, another group of proteins with molecular weights of 40,000 to 43,000 is also a product of the proteolysis of normal semen but does not show up readily in oligospermic seminal plasma. Therefore, there is a need to examine proteolysis and its inhibition and the possible contribution by sperm degradation to the appearance of some proteins in seminal plasma by studying seminal plasma of individuals with normospermia, oligospermia, and azoospermia as well as the effect of protease inhibitors on the presence and detection of any proteins.

It is not clear whether the proteins (molecular weights = 20,000 to 23,000) that we found in the seminal plasma of oligospermic men reflect subfertility or give rise to infertility. If proteolysis of spermatozoa is accelerated in the ejaculates of oligospermic men, the number of spermatozoa available for ascent into the female reproductive tract could be reduced. On the other hand, such accelerated proteolysis may eliminate abnormal or nonviable spermatozoa as a means of ensuring selection of the more optimal spermatozoa, since proteolysis also occurs in normal semen but at a slower rate. Further studies are necessary to clarify these mechanisms.

In conclusion, we have found accelerated proteolysis in the semen of oligospermic men and it is readily demonstrable early after ejaculation and liquefaction by two-dimensional gel electrophoresis. This derangement could be a contributory factor to the infertility of oligospermic men.

The effect of insulin on aromatase activity in isolated human endometrial glands and stroma

John F. Randolph, Jr., M.D., Simon Kipersztok, M.D., Jonathan W. T. Ayers, M.D., Rudi Ansbacher, M.D., M.S., Helle Peegel, M.S., and K. M. J. Menon, Ph.D.

Hyperinsulinemic states have been associated with an increased incidence of estrogen-dependent endometrial neoplasia. To study the effect of insulin on the ability of endometrium to aromatize androgens to estrogens, late proliferative endometrium was obtained from normally cycling women at the time of indicated surgery, separated into component glands and stroma, and grown to confluence. Separated gland and stromal cultures were incubated in triplicate with increasing insulin concentrations and epidermal growth factor. Aromatase activity was assayed by the production of tritiated water from tritium-labeled androstenedione. The activity was noted to increase proportionally with increasing concentrations of insulin >10 U/ml, and the effect was specific. These data suggest the following conclusions: (1) Insulin stimulates aromatase activity in both endometrial glands and stroma; (2) hyperinsulinemia may predispose to endometrial neoplasia by enhancing endogenous endometrial estrogen production. (Am J Obstet Gynecol 1987;157:1534-9.)

Key words: Aromatase, endometrium, epidermal growth factor, insulin

Endometrial neoplasia has been linked epidemiologically to both long-term unopposed estrogen exposure and hyperinsulinemia as independent risk factors.[1, 2] The mechanisms linking estrogens and endometrial neoplasia have been studied extensively, whereas the association between insulin and endometrial neoplasia remains largely unexplored. Several recent lines of evidence, when taken together, suggest a mechanism for this association.

Tseng et al.[3] demonstrated the ability of endometrium to convert androgens to estrogens by aromatization, which suggests a potential role for endogenously produced estrogen in local stimulation of endometrial proliferation. Garzo and Dorrington[4] described augmentation of follicle-stimulating hormone (FSH)–induced aromatization in granulosa cells by insulin. Sheets et al.[5] demonstrated the existence of endometrial insulin receptors, which documents binding of insulin by endometrial plasma membranes. A possible role for endogenous endometrial stimulation by insulin-induced augmentation of endometrial aromatization was thus postulated.

This study was undertaken to test the hypothesis that insulin modulates aromatase activity in human proliferative endometrium.

Material and methods

Endometrium was obtained by curettage from normally cycling parous women undergoing elective laparoscopic tubal sterilization on days 9 through 12 of the menstrual cycle. All women were 25 to 35 years of age, were not receiving hormones, were euthyroid, and had no evidence of hepatic dysfunction. This study was approved by the Human Research Committee of the University of Michigan Medical Center.

Endometrial separation and culture. Endometrial specimens were placed in 50 ml of iced, sterile, normal saline solution and transported to the laboratory where they were processed immediately. Stromal cells were separated from glands by a modification of the method of Liu and Tseng.[6] The tissue was washed with calcium and magnesium-free Earle's balanced salt solution (Gibco, Grand Island, N.Y.) and minced into 1 mm^3 fragments. Tissue separation was achieved by digesting the fragments (0.2 to 0.5 gm tissue/5 ml) in Earle's balanced salt solution containing collagenase (300 U/ml, Cooper Biomedical, Malburn, Penn.), deoxyribonuclease (1 μg/ml, Cooper Biomedical), bovine serum albumin (3 mg/ml, bovine serum albumin fraction V, Sigma Chemical Co., St. Louis, Mo.), gentamicin (50 μg/ml, Elkins-Sinn, Inc., Cherry Hill, N.J.), and mycostatin (2 U/ml, Gibco) at 37° C in a water bath with constant stirring. Free stromal cells were removed by centrifugation from the collagenase solution at 15-minute intervals during the 2-hour digestion period

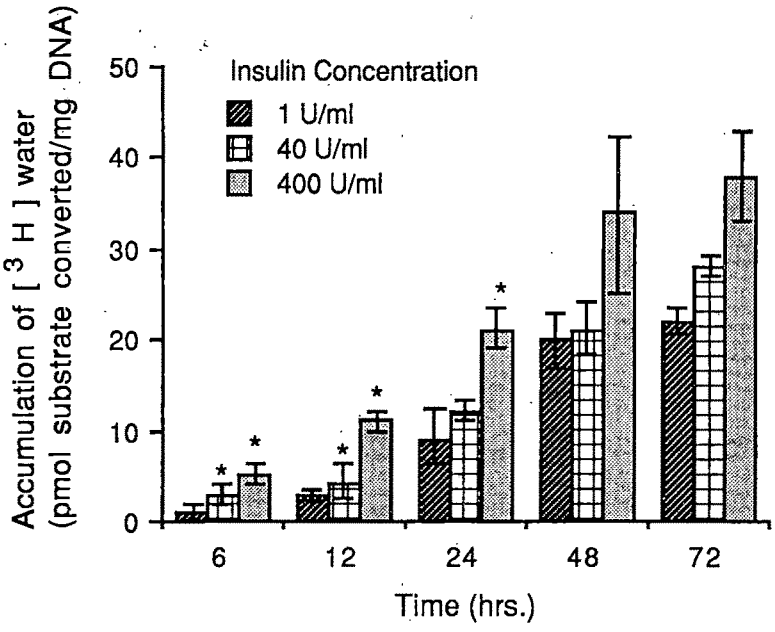

Fig. 1. The effects of time and insulin concentration on aromatase activity in isolated proliferative endometrial stromal cells in confluent monolayer culture. *Bars* represent mean values ± SEM. *DNA* = Deoxyribonucleic acid. * = $p < 0.05$ versus controls.

and resuspended in culture medium A (McCoy's modified 5A medium containing 10% fetal calf serum (Gibco), gentamicin (50 μg/ml, Elkins-Sinn) and mycostatin (2 U/ml, Gibco). Cell viability averaged 70% on the basis of the trypan blue exclusion method. When necessary, erythrocytes were removed by layering the crude stromal cell suspension over Ficoll-Hypaque (Pharmacia, Inc., Piscataway, N.J.) and centrifuging at 700 × g for 15 minutes. After the 2-hour stromal cell separation, the remaining glands were incubated with collagenase for an additional 45 minutes. The stromal and gland cell suspensions were washed three times with medium A and plated into 35 by 10 mm culture dishes (Falcon Plastics, Becton, Dickinson & Co., Oxnard, Calif.) at 2×10^6 cells/2 ml medium A per dish and incubated at 37° C under water-saturated 95% air/5% carbon dioxide. Confluence was reached 3 to 4 days after plating. Morphologic assessment of the separated stromal and gland cell cultures was made by the method described by Liu and Tseng,[6] and a similar 95% purity was found.

Aromatase assay. Aromatase activity was assayed by a modification of the method of Thompson and Siiteri[7] on the basis of the equimolar production of tritiated water during the aromatization of (1β-^{3}H)-androstenedione. Cultures were rinsed with 0.1% bovine serum albumin–McCoy's medium and incubated at 37° C under water-saturated 95% air/5% carbon dioxide with 0.5 μCi (1β-^{3}H)-androstenedione (27.8 Ci/mmol, New England Nuclear, Boston, Mass.). At the completion of each incubation, the culture dishes were placed on ice and the medium was removed and assayed for the incorporation of tritium into tritiated water. In brief, 1 ml of spent media was mixed with trichloroacetic acid (10% final concentration), placed on ice for 15 minutes, and then centrifuged at 3000 × g for 10 minutes. The supernatant was extracted with 3 ml of chloroform. An aliquot of 1 ml of the aqueous layer was added to the charcoal pellet obtained from 1 ml of 5% Norit-A (Fisher Scientific Co., Fairlawn, N.J.), mixed, and placed on ice for 15 minutes. After centrifugation for 15 minutes at 3000 × g, 10 ml Safety-Solve (Research Products International Corp., Mt. Prospect, Ill.) was added to the supernatant, which was then counted in a scintillation counter. Cells were washed, scraped from the dishes, and assayed for deoxyribonucleic acid according to the method of Burton.[8] All cultures were run in triplicate and each assay included triplicate blanks receiving all reagents but no cells. Values obtained for blanks were subtracted from all assay values. This laboratory has previously verified this assay and demonstrated a good correlation between tritiated water produced and total estrogen production.

Statistical analysis was performed by a two-tailed Student's t test and p values were calculated by the least-squares method. Statistical significance was defined as $p < 0.05$.

Results

As a preliminary study to establish the presence of an insulin effect and to determine an optimal time

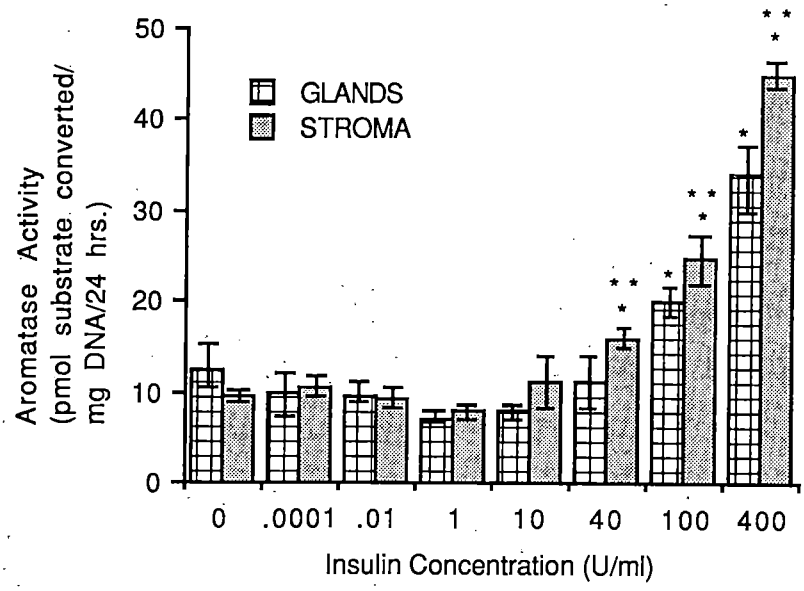

Fig. 2. The effect of insulin concentration on aromatase activity in isolated proliferative endometrial gland and stromal cells in confluent monolayer culture. * = $p < 0.05$ versus controls. ** = $p < 0.05$ versus gland cells.

course for assays, stromal cultures were incubated with 7 nmol/L (1β-^{3}H)-androstenedione and 1, 40, or 400 U/ml insulin for periods of 6, 12, 24, 48, and 72 hours. The endometrial stroma, as depicted in Fig. 1, demonstrated a statistically significant increase in aromatase activity at the highest insulin concentration through 24 hours. The 48- and 72-hour assays demonstrated an apparent increase in aromatase activity, but the standard error was large and statistical significance was not reached. Approximately 25% detachment of cells was noted in the cultures after 24 hours at 400 U/ml insulin, which perhaps accounts for the variability and lack of significance. Therefore, all subsequent assays used a 24-hour incubation period. A statistically significant increase in aromatase activity was also seen in the presence of the 40 U/ml insulin concentration at 6 and 12 hours of incubation.

To determine the effect of insulin concentration on aromatase activity in both isolated glands and stroma, separated gland and stromal cell cultures were incubated with 7 nmol/L androstenedione for 24 hours with increasing concentrations of insulin as depicted in Fig. 2. A statistically significant increase in aromatase activity was noted in the gland cell cultures at all insulin concentrations of ≥100 U/ml and in the stromal cell cultures at all insulin concentrations of ≥40 U/ml. The increase in aromatase activity at each insulin concentration was greater in the stromal cell cultures than in the gland cell cultures. The increase in aromatase activity with increase in insulin concentration was nearly linear in the gland cell cultures and demonstrated some falloff at higher insulin concentrations in the stromal cultures, presumably because of cell detachment.

The kinetics of both the basal and the insulin-induced aromatase activity were studied as summarized in part in Fig. 3. Separated cell cultures were incubated with 10, 110, and 210 nmol/L (1β-^{3}H)-androstenedione and 0, 10, and 100 U/ml insulin. The Michaelis-Menten constant for the reaction of each cell type remained constant at all insulin concentrations, whereas the maximum velocity increased significantly at higher concentrations.

Specificity of the insulin effect was examined by incubating separated cultures with 200 ng/ml epidermal growth factor and parallel cultures with 1, 10, and 100 U/ml insulin. As demonstrated in Fig. 4, epidermal growth factor did not stimulate an increase in aromatase activity, whereas insulin stimulated an increase at both 10 and 100 U/ml. No difference was noted in insulin induction of aromatase activity at any concentration between the two cell types in this experiment.

Comment

The positive correlation between endometrial aromatase activity and insulin concentration noted in this study provides the first evidence for a physiologic link between insulin and endometrial neoplasia. The clinical association between hyperinsulinemia and endometrial neoplasia has been well recognized,[1,2] but the physiologic basis for this association has remained obscure. Unopposed estrogen stimulation of endometrium has been well established as the major risk factor for en-

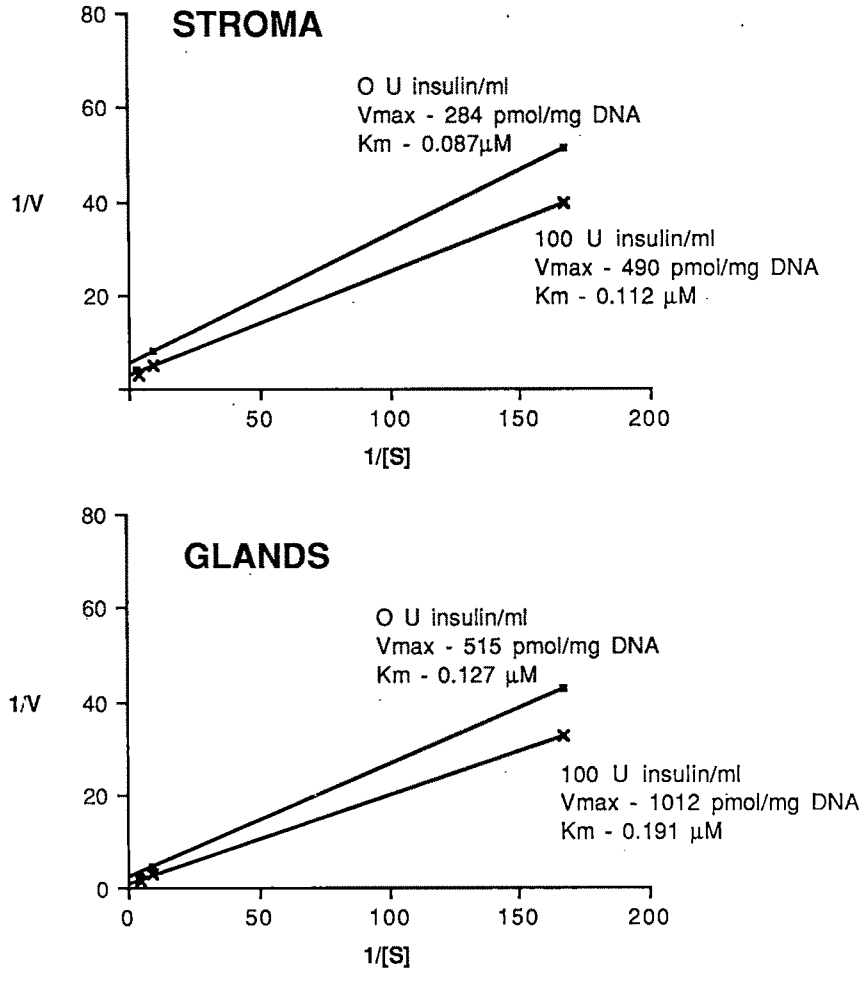

Fig. 3. Enzyme kinetics of basal and insulin-stimulated aromatase activity in isolated endometrial gland and stromal cultures. *Vmax* = Maximum velocity. *Km* = Michaelis-Menten constant.

dometrial neoplasia, and the discovery that endometrium was capable of endogenously producing estrogen[3] has led to speculation on the role of locally produced estrogen in the genesis of endometrial neoplasia. With the findings that endometrium harbored receptors for insulin[5] and that insulin can augment aromatase activity in another reproductive tissue, granulosa cells,[4] the possibility of insulin-induced aromatase activity in endometrium was entertained. This study demonstrates for the first time that insulin can increase aromatase activity in endometrium.

Endometrial aromatase activity has been shown to be influenced by a number of factors. Tseng[9] demonstrated that progesterone markedly increased aromatase activity and that estradiol augmented this progesterone-induced increase in aromatase activity. Estradiol alone did not change aromatase activity. Tseng et al.[10] demonstrated that a number of synthetic progestins increased aromatase activity, with medroxyprogesterone acetate demonstrating the greatest stimulation. In that same study, no increase in aromatase activity was noted with 17α-hydroxyprogesterone, corticosteroids, or androgens.

Most recently, Tseng et al.[11] reported on the effects of relaxin, insulin, and epidermal growth factor on aromatase activity in cultured human endometrial stromal cells. Relaxin alone did not increase aromatase activity but augmented the stimulatory effect of medroxyprogesterone acetate or medroxyprogesterone acetate and estradiol. Insulin, in concentrations of 0.1, 1, and 10 U/ml, did not augment the medroxyprogesterone acetate– and estradiol-induced increase in aromatase activity, but the effect of insulin alone was not reported. Epidermal growth factor (100 ng/ml) alone did not significantly change aromatase activity, a result consistent with the findings of the current study.

Late proliferative endometrium was chosen in this initial study of insulin modulation of aromatase activity since it demonstrates greater activity than secretory endometrium[3] and was felt to be the normal endo-

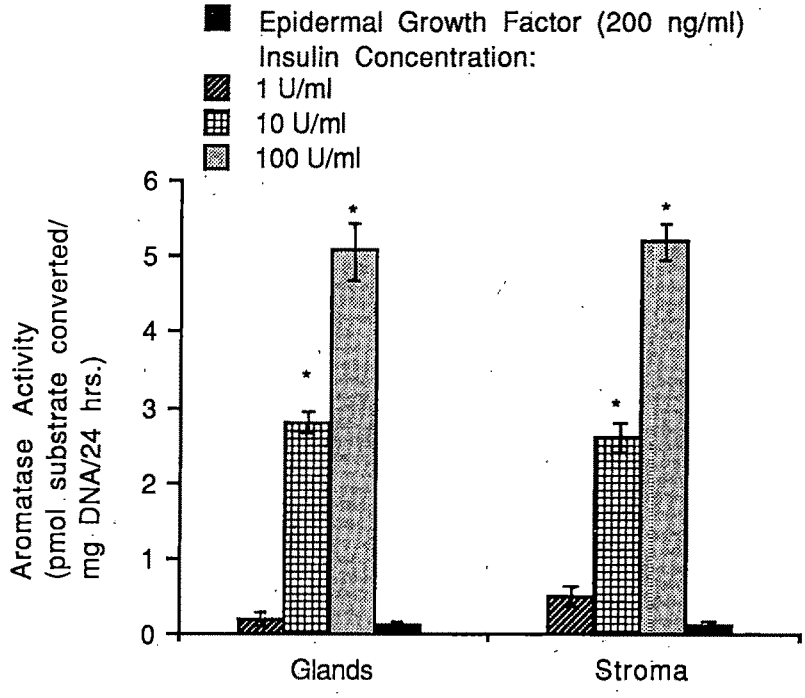

Fig. 4. The effect of insulin and epidermal growth factor on aromatase activity in isolated proliferative endometrial gland and stromal cells in confluent monolayer culture. * = $p < 0.05$ versus controls.

metrium most closely resembling endometrium undergoing chronic unopposed estrogen stimulation. Separated gland and stromal cell cultures were used to determine if a difference in the aromatase activity in the two principal tissues in endometrium could be found. Since most endometrial carcinomas are adenocarcinomas of epithelial origin, the possibility of an enhanced response to insulin in glandular tissue with greater estrogen production and more proliferation was proposed. Such an enhanced response in gland cells was not seen, with a similar or slightly decreased stimulation actually noted. As with any separated cell culture system, purity of the culture was a concern. The characteristic morphologic features of the two cell types in culture permitted the accurate determination of purity on morphologic criteria, as described by Satyaswaroop et al.[12] and by Liu and Tseng.[6]

The assay to determine aromatase activity was initially described and verified by Thompson and Siiteri[7] and subsequently verified by a number of authors, including Tseng et al.[10] The concentrations of insulin required to demonstrate an increase in aromatase activity were four to five orders of magnitude higher than the physiologic concentrations of insulin in the nondiabetic, nonobese human being. The phenomenon is not unique to this particular cell system, with many in vitro systems requiring supraphysiologic concentrations of effector to produce a given response. A number of enzymes capable of metabolizing insulin may be present in this cell system and therefore decrease the effect of insulin. As insulin is also well known to adhere to plastic, the effective concentration may have been decreased by adherence to the culture dishes.

The effect of insulin on the aromatase enzyme system appears to be an increase in maximum velocity. The exact mechanism of this effect remains to be investigated.

Epidermal growth factor was used to investigate specificity because of its growth-promoting effects and known binding to endometrium.[5] The enhancement of aromatase activity by insulin seems to be specific since epidermal growth factor did not have any detectable effect. However, the high concentrations of insulin required to demonstrate an effect suggests that other factors, such as the insulin-like growth factors, may play a role. Studies to investigate such a possible role are currently being made.

These initial findings suggest a number of subsequent studies including steroid-induced insulin receptor dynamics modulating aromatase activity, possible stimulation by other polypeptide hormones, such as gonadotropins and prolactin, and studies throughout the menstrual cycle to determine if a cyclic pattern of response exists.

This study demonstrates that insulin stimulates aromatase activity in both the isolated glands and stroma from human proliferative endometrium. This finding suggests an explanation for the clinical association of

hyperinsulinemia and endometrial neoplasia by an insulin-induced augmentation of endogenous endometrial estrogen production.

Uterine artery Doppler velocimetry: The significance of divergent systolic/diastolic ratios

Harold Schulman, M.D., James Ducey, M.D., George Farmakides, M.D., Edwin Guzman, M.D., Denise Winter, R.N., B.S.N., Barbara Penny, R.N., and Chi-Lee, B.S.

Mineola, New York

Continuous wave Doppler studies were carried out on both uterine arteries in 71 pregnant women from the twentieth week of gestation onward. Analysis of the waveform included the systolic/diastolic ratio and the presence or absence of a diastolic notch. In the current study, these ratios from 31 women with left/right systolic/diastolic difference, (between left and right uterine arteries) were compared with those of women having normal ratios. A normal left/right systolic/diastolic ratio difference of 0.3 with SD of 0.3 was found. When the left/right difference was plotted against the left/right averaged systolic/diastolic ratio, a correlation coefficient of 0.7 was noted ($p < 0.001$). Significant outcome differences were noted between normal and abnormal left/right difference systolic/diastolic ratios in the perinatal parameters of gestational age at delivery, fetal weight, pregnancy-induced hypertension, proteinuria, and intrauterine growth retardation. Divergent uterine artery ratio findings are a result of one artery being the dominant supplier to the placenta. The majority of women with an elevated systolic/diastolic ratio seem to have divergent uterine blood supply to the uterus and placenta. These data suggest that errors in placentation site contribute to the development of preeclampsia and growth retardation in the fetus. (AM J OBSTET GYNECOL 1987;157:1539-42.)

In previous studies we noted that when there was an elevated uterine artery systolic/diastolic ratio as measured by a continuous wave Doppler system, an adverse perinatal outcome[1] and a maternal hypertensive syndrome were likely. From the beginning of the study we measured the waveforms from both the left and the

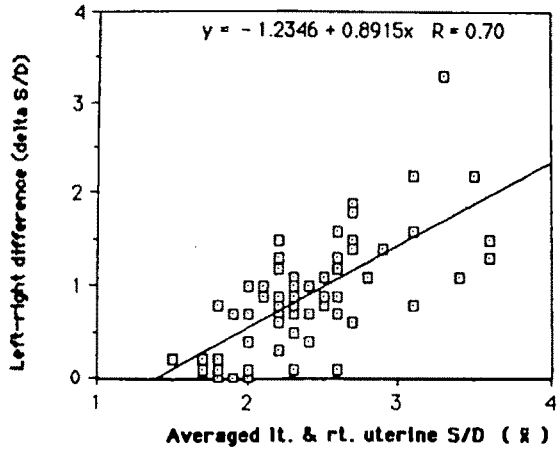

Fig. 1. Data from left and right uterine arteries.

right uteroplacental artery, calculated a systolic/diastolic ratio, and averaged the values from both sides.[2] The reason for making these measurements was because it was noted that in some cases there appeared to be considerable differences between the systolic/diastolic ratio of the left and right vessels. When this occurred, the difference was frequently associated with implantation of the placenta on the lateral wall of the uterus. The vessel on the same side of the placenta demonstrated the lower systolic/diastolic ratio with the disappearance of the diastolic notch.

As our number of observations increased, we began to suspect that in some cases of pregnancy-associated hypertension, the regression to the early pregnancy waveform occurred first in the antiplacental vessels. In this article we will present an analysis of the normal and abnormal divergence of the uterine artery systolic/diastolic ratio and the associated consequences of such an event.

Material and methods

Doppler studies were carried out with a continuous wave transducer with a 6.5 mW/cm^2 power density. The woman was examined in the supine position with a tilt to the left or right, depending on which vessel was being studied. The probe was directed to the paracervical area in the lower quadrants at the site of the uterine vessels. Four waveforms equal in intensity and of maximum size were obtained from each side. A systolic/diastolic ratio was computed and these values were totaled and averaged. Umbilical artery velocimetry was calculated at the same time. All vessels were identified by pattern recognition. Real-time ultrasound was used when we had difficulty in locating the desired vessel pattern. Previously it had been determined that the interobserver error for this examination is 4% with a maximum potential error of 10%. One hundred women with normal pregnancy outcomes were studied prospectively to establish normal values for the left and right uterine arteries and to compute the range of difference between the two. These studies were carried out from the twentieth week onward and were done monthly. Forty subjects from this group were selected randomly and compared with 31 women with elevated systolic/diastolic ratios seen concurrently during the same time period. The women with elevated ratios were examined at least twice with a minimum of a 3-day interval.

Analyses consisted of regression curves, correlation coefficients, and Student's t tests. An Apple computer with a statistical software system was used for these calculations. In this series velocimetry data were not used to influence clinical management.

Results

Fig. 1 depicts the regression curve analysis of the left/right difference in the systolic/diastolic ratio and the averaged systolic/diastolic ratio from both sides. It was determined from our prospective studies that the normal difference, Δ, between the two uterine systolic/diastolic ratios was 0.3 with an SD of 0.3. Hence "abnormal" was defined as ≥ 1 (mean + 2 SD rounded to 1). In previous studies it was determined that the abnormal averaged systolic/diastolic ratio was >2.6 after 26 weeks' gestation. The correlation coefficient was 0.7 between the Δ and averaged values, which was highly significant.

Next, the four combinations of vessel patterns were evaluated with the normal and abnormal Δ and averaged systolic/diastolic values were used as the matrix (Table I). In this way it was hoped to determine which was the more significant variable, the Δ value or the elevated systolic/diastolic ratio.

Table I reveals that only three women with an elevated systolic/diastolic ratio had normal Δ values of <1. Thus, 81% of the women with elevated systolic/diastolic ratios had a significant divergence in flow velocity between the right and left vessels. In Table I those women with normal ratios and Δ values were used as the control population in this study, but the fact that 14% had hypertension and 14% had pregnancy-induced hypertension was noted. Those women with either abnormal Δ values or abnormal ratios experienced less than optimal pregnancy outcomes and perinatal courses when compared with the group with normal ratios and Δ values.

Both groups with abnormal Δ values had earlier deliveries and smaller infants. The umbilical systolic/diastolic ratios in most of these small infants were elevated; this finding is similar to the data reported previously.[3] The combined abnormal group had more instances of pregnancy-induced hypertension. A normal uterine systolic/diastolic ratio but abnormal Δ was

associated with significantly less pregnancy-induced hypertension ($p < 0.05$) and a trend to less intrauterine growth retardation. Also, fewer deliveries occurred before 37 weeks than occurred when both parameters were abnormal.

We examined the relationship between the lower systolic/diastolic ratio and the ultrasonic placental location and could not demonstrate a clear correlation. The majority of placentas were anterolateral or posterolateral and blood supply to the placentas was variable in these women. If the placenta was exactly lateral, the systolic/diastolic ratio was initially lower on that side. In the 28 women with elevated left/right differences analyzed in terms of placental site, half of the sites were on the left lateral uterine wall and the other half on the right wall.

Comment

Previous reports from our laboratory and others have demonstrated the relationship between abnormal uterine artery velocity waveforms and maternal hypertensive syndromes. Campbell et al.[4] and Trudinger et al.[5, 6] primarily studied the subplacental arcuate vessels identified by real-time ultrasound. Campbell et al.[7] in a recent prospective report examined both vessels but attempted to classify them as placental and antiplacental. We think this is an error because the development of collaterals is unpredictable, and we could not develop a correlation between them because of the large number of anterolateral-posterolateral implantations. When the placenta is anterolateral or posterolateral, there may be also uterine levorotation or dextrorotation, which make the location of the uterine vessels uncertain.

It is interesting that when abnormal differences between the left and right vessels exist, the abnormal differences appeared to have an adverse impact on the pregnancy even when the combined ratio was normal. When both parameters were abnormal the effect on the pregnancy was even more significant. These data, then, would suggest that dissimilar uterine flow velocity may be a significant pathophysiologic event. Noteworthy, also, is the fact that few women had an elevated systolic/diastolic ratio without having divergent velocities between the left and right arteries.

The existence of divergent blood flow velocity may be unique to human beings. Most animals have a two-horned uterus, with only one vessel serving the placenta or placentas. In primates, there is often a bilobed placenta, which probably mandates trophoblastic invasion into the spiral arteries of both uterine vessels. This invasion of the spiral arteries, together with the resultant destruction of the media of the artery, is the probable cause of the lowered uterine artery resistance, the lowering of the systolic/diastolic ratio, and the diastolic notching. One could speculate that the absence of a natural toxemic animal model could be accounted for by this unique vascular relationship.

Medical literature is rich with studies attempting to demonstrate a relationship between the placental blood supply and the development of pregnancy-induced hypertension. Little and Friedman[8] could not demonstrate a relationship between placental location and clinical disease. Chesley[9] has reviewed the experiments carried out in this century on animals and humans in which alteration of uterine blood flow was studied or created to assist in the understanding of pregnancy hypertension. He concluded: "... placental ischemia typically is associated with preeclampsia but it may be secondary rather than causative."

Until Doppler technology was developed it was not possible to study uterine blood flow sequentially

throughout pregnancy. Doppler velocity studies have demonstrated that a predictable pattern of change as pregnancy progresses exists, a pattern completed at the twenty-sixth week of gestation. Pregnancy-induced hypertensive syndromes and fetal growth retardation are seen when these expected changes do not occur or when they do evolve and regress to an earlier pattern.

Some pregnancy hypertension syndromes are seen when primary reduction of velocity flow on the fetal side of the placenta occurs, with normal maternal vasculature.[10, 11] Hypertension not appearing until the pregnancy is near term frequently shows no evidence of diminished maternal or fetal flow velocity.

These data suggest that some women with pregnancy-induced hypertension have a dominant unilateral placental blood flow. Whether this condition and the associated adverse perinatal outcome are amenable to modification will be determined by future studies on placentation and clinical prospective trials.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

The effects of membrane permeability and binding by human serum proteins on steroid influx into the rabbit uterus

Kenneth A. Steingold, M.D., William M. Pardridge, M.D., Howard L. Judd, M.D., and Gautam Chaudhuri, M.D., Ph.D.

Los Angeles, California

The effects of capillary membrane permeability and binding by human plasma proteins on the influxes of tritium-labeled steroids from the circulation into the uterus were measured in vivo in anesthetized rabbits with a tissue-sampling, single injection technique, and the results were compared with similar studies involving rats. Rabbits were used in this study because this species, unlike the rat, has a sex steroid–binding protein. The impact of capillary membrane permeability markedly varied with different steroids and did not completely parallel the lipid solubility of these compounds. The addition of plasma proteins to the injection vehicle had varied inhibitory effects on the in vivo extractions by the uterus. These in vivo extraction values could not be predicted from in vitro studies of steroid binding to plasma proteins and the results underscore the importance of performing in vivo studies so that we may have a better understanding of the bioavailability of steroids to tissues. (Am J Obstet Gynecol 1987;157:1543-9.)

Key words: Steroids, microvasculature permeability, plasma proteins

We have emphasized in previous studies[1, 2] that factors affecting the differential availability of steroids in the circulation to tissues (e.g., the capillary permeability barriers and plasma protein–binding effects) are important determinants of the biologic responses exerted by these hormones. Our work relates to factors controlling the exit of steroids from the microcirculation to the extravascular space and does not address issues relating to the intracellular environnment. These earlier studies were performed in the rat,[1, 2] a species that lacks a specific sex steroid–binding serum protein.[3] The present study was undertaken in order to evaluate whether the control mechanisms of hormone delivery observed in rats are applicable to another species. In the study, a model was developed to assess transport of circulating steroids into the uterus of the rabbit. This species was chosen because it has an endogenous circulating sex steroid–binding protein (r-SBP),[4] and the uterus was selected since the rabbit spontaneously develops endometrial cancer.[5] Thus, the mechanisms that influence transport of circulating estrogens into this organ may be important in the initiation of this disease.

Material and methods

The following isotopes with the manufacturer's specific activities were purchased from New England Nuclear, Boston, Mass.: n-[1-^{14}C]butanol, 1.0 mCi/mmol; [2,4,6,7-N-^{3}H]estrone, 88.5 Ci/mmol; [2,4,6,7,16,17-N-^{3}H]estradiol, 140 Ci/mmol; [2,4,6,7-N-^{3}H]estriol, 105 Ci/mmol; [6,7-N-^{3}H]estrone sulfate, 59.0 Ci/mmol; [1,2,6,7-N-^{3}H]progesterone, 101 Ci/mmol; [1,2,6,7-N-^{3}H]corticosterone, 105 Ci/mmol; [1,2,6,7-N-^{3}H]cortisol, 88.3 Ci/mmol; [1,2,6,7,16,17-^{3}H(N)]testosterone, 141 Ci/mmol; [1,2,4,5,6,7,16,17-^{3}H(N)]-dihydrotestosterone, 172 Ci/mmol; and [^{125}I]iodine, 2 mCi/mmol. Unlabeled N-isopropyl *p*-iodoamphetaminne was a gift from Dr. James Lamb, Medi-Physics Inc., Emoryville, Calif. Bovine serum albumin was purchased from Sigma Chemical Co., St. Louis, Mo. Human serum obtained from pregnant women in the third trimester was pooled and frozen.

The radiochemical purity of all isotopes was assessed by thin-layer chromatography with radiochromatogram scanning (Packard Instrument Co., Downers Grove, Ill.) of a small aliquot of the radiolabeled steroids; only a single radioactive peak was found for each steroid. Labeled steroids and conjugates were supplied by the manufacturer in solvent that was evaporated before the isotopes were mixed in buffered Ringer's solution containing 0.1% bovine serum albumin.

Iodination of the IMP and tritiation of bovine serum albumin. Labeling of IMP was achieved by an [^{125}I]iodine exchange reaction as previously described.[6] The isotope had a specific activity of 150 μCi/μmol and was 95% to 98% radiochemically pure, as judged by

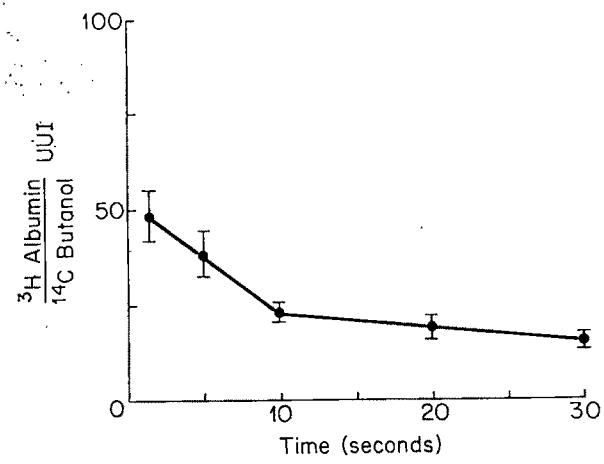

Fig. 1. Mean (±SE) uterus influx index for [^{125}I]bovine serum albumin relative to [^{14}C]butanol at 2, 5, 10, 20, and 30 seconds after injection into the lower abdominal aorta. The values are the mean of four to six animals per point.

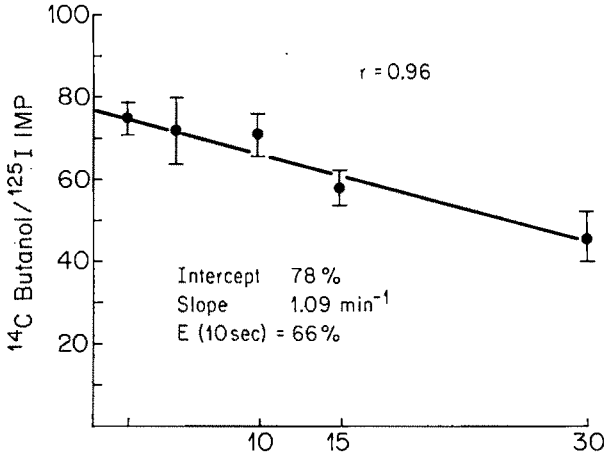

Fig. 2. The ln uterus influx index of [^{14}C]butanol relative to [^{125}I]IMP is plotted versus time after aortic injection. The intercept of 78% indicates that IMP is more diffusible than butanol. The slope of the plot provides the rate constant for butanol washout. The extraction of butanol at 10 seconds is 66%.

thin-layer chromatography.[6] Bovine serum albumin was radiolabeled by reductive methylation and tritiation of albumin lysine residues with [^{3}H]sodium borohydride as previously described.[7] The trichloroacetic acid precipitability of the [^{3}H]albumin was >99%.

The unidirectional influx of test substance into the uterus was measured by a tissue-sampling, single-injection technique similar to that described in studies with rats.[1] The animals used were 4 to 4.5 kg New Zealand White female rabbits. The animals were anesthetized with a mixture of halothane and 100% oxygen, placed in the supine position, and subjected to a vertical laparotomy incision. The right common iliac and left femoral arteries were clamped, and the lower abdominal aorta was isolated. The aorta was cannulated with a 25-gauge needle for rapid (0.5 second) injection of 500 μl of the isotopes in 10 mmol/L Hepes-buffered Ringer's solution (pH = 7.4). The test substances used were either [^{125}I]IMP, [^{3}H]albumin, or the tritium-labeled steroids. The diffusible reference was [^{14}C]butanol.[1, 2] At a predetermined time after the rapid, bolus injection, the uterus was surgically excised. The left uterine horn was minced and about 0.5 to 1 gm of tissue was solubilized in 2 ml Soluene 350 (Packard Instrument Co., Downers Grove, Ill.). An aliquot of the injection solution was similarly prepared for double-isotope liquid scintillation counting. Isotope counts per minute were converted to disintegrations per minute by standard quench corrections. The uterus influx index for [^{3}H]albumin or test [^{3}H]steroid relative to [^{14}C]butanol was calculated as follows:

$$\text{Uterus influx index} = \frac{[^{3}H/^{14}C]\text{uterus}}{[^{3}H/^{14}C]\text{injection solution}} \times 100$$

To ascertain the flow characteristics of the rabbit uterus, the uterus influx index of albumin, which is relatively nondiffusible at the capillary membrane,[8] was determined by injecting 500 μl Ringer's solution containing 5 μCi/ml [^{3}H]albumin and 0.5 μCi/ml [^{14}C]butanol, with tissue sampling at 2, 5, 10, 20, and 30 seconds. Results are presented in Fig. 1. By 10 seconds the uterus influx index of albumin had fallen to a value of 23% and was essentially unchanged at 20 and 30 seconds. This indicated that the injection bolus had been largely cleared from the uterine vasculature by 10 seconds, and whatever albumin that persisted in the uterus at that time represented residual tracer that presumably leaked into the interstitial space or was adherent to the endothelial lining. The washout of butanol from uterine cells from 10 to 30 seconds presumably accounted for the maintenance of the uterus influx index during this period. Therefore, all subsequent studies were performed with tissue sampling 10 seconds after injection, a time sufficiently long to allow substances remaining in the vasculature to leave the organ by way of the venous system but sufficiently short to minimize the loss of compounds passing through the wall of the vasculature into the organ's extravascular space, then reentering the circulation. These compounds are washed out of the organ through the venous system.

The uterus influx index = E_T/E_R where E_T and E_R represent the extractions of the test compound ([^{3}H]albumin, [^{3}H]steroids) and the reference compound ([^{14}C]butanol), respectively, at the appropriate times after injection. The E_T and E_R represent the maximal extraction of unidirectional influx into the uterus,

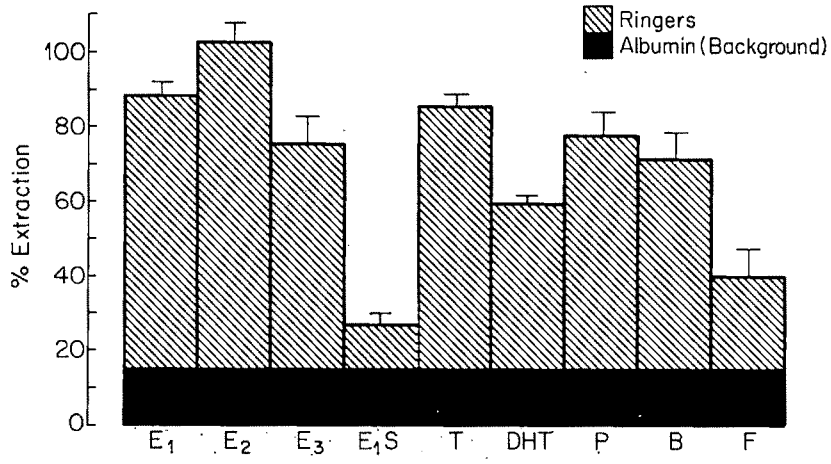

Fig. 3. The uterine extraction (percentage) in the rabbit of labeled estrone (E_1), estradiol (E_2), estriol (E_3), progesterone (P), testosterone (T), dihydrotestosterone (DHT), corticosterone (B), cortisol (F) and estrone sulfate (E_1-S) in Ringer's solution relative to that of [^{14}C]butanol is shown. Data are the mean ± SE (three to eight animals per point). The uterine extraction of albumin refers to nonspecific isotope remaining 10 seconds after injection in the uterine capillaries.

i.e., E (time 0), minus the back diffusion of test or reference compounds during the period between the bolus flow through the uterus and its removal. The uterus influx index may be converted to E_T if E_R is known (E_T = uterus influx index × E_R). It has been assumed that E_R = 1.0 for [^{14}C]butanol.[6] However, recent studies with IMP have shown that butanol, unlike IMP, is not always completely cleared by capillary beds.[6] Therefore, the E_R (time 0) and E_R (10 seconds) for [^{14}C]butanol were estimated in the present studies by comparing the uptake of [^{11}C]butanol relative to [^{125}I]IMP. In preliminary studies, the ln (disintegrations per minute per gram per deciliter injected dose) for [^{125}I]IMP was plotted versus time after injection. No significant difference in values of ^{125}I was found from 2 to 30 seconds, thereby confirming that [^{125}I]IMP, once sequestered by the uterus, does not have a significant efflux back into the microvasculature within 30 seconds, similar to what occurs in the brain.[6] The extraction of [^{14}C]butanol reference was next calculated by determining the uterus influx index of [^{11}C]butanol relative to [^{125}I]IMP at 2, 5, 10, 15, and 30 seconds. A regression line was thus generated (Fig. 2). The intercept at time 0 was the maximal butanol extraction relative to [^{125}I]IMP, i.e., 78%. The extraction of butanol at 10 seconds was found to be 66%. With this value, all uterus influx index determinations were converted to uterine extraction (E_T) values by the formula: E_T = uterus influx index × 0.66. The uterine extraction of albumin at 10 seconds, 15%, was calculated from the uterus influx index for [^{3}H]albumin, 23%, and this value represented the background extraction.

The tracer concentrations of the tritium-labeled steroids varied from 25 to 50 nmol/L, and that of tritium-labeled conjugated hormones ranged from 50 to 100 nmol/L. The ratio of tritium to carbon 14 was kept between 10 and 30. The injection vehicles included buffered Ringer's solution (pH 7.4, 5 mmol/L Hepes) and contained either 0.1% or 4% bovine serum albumin or pooled third-trimester pregnant human serum. The presence of 0.1% bovine serum albumin in the control injections promoted solubility of the labeled steroids in aqueous solutions. When serum was used as the injection vehicle, the concentrations of labeled test substances were deliberately set to be less than the concentration of unbound sex hormone–binding globulin sites, as determined by a selective ammonium sulfate precipitation technique with a [^{3}H]dihydrotestosterone reference.[9]

The fraction of total steroid hormone in human pregnancy serum that was available for influx into the tissues was calculated as follows:

$$\text{Percent available for influx} = \frac{E_{HPS} - E_{BKG}}{E_{control} - E_{BKG}} \times 100$$

where E_{HPS} was the extraction of steroids when human pregnancy serum was used as the vehicle, E_{BKG} was the background value of the method represented by uterine extraction of membrane-impermeable albumin (15%), and $E_{control}$ was the extraction of test substance after injection in Ringer's solution containing 0.1% bovine serum albumin.

The percents of free (dialyzable) fractions of labeled steroids in undiluted human pregnant serum were measured with centrifugal ultrafiltration dialysis.[10] To determine the fraction of steroid that was free and albumin bound, the serum was incubated at 60° C for 30 minutes. The free (dialyzable) fraction was then re-

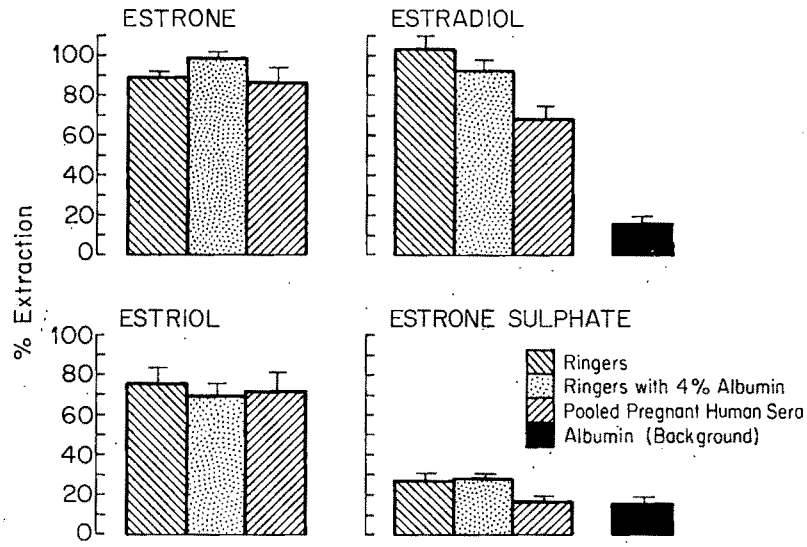

Fig. 4. The mean uterine extractions (percentage) in the rabbit of estrone, estradiol, estriol, and estrone sulfate relative to that of [^{14}C]butanol are shown; injection solutions contained variable amounts of serum proteins.

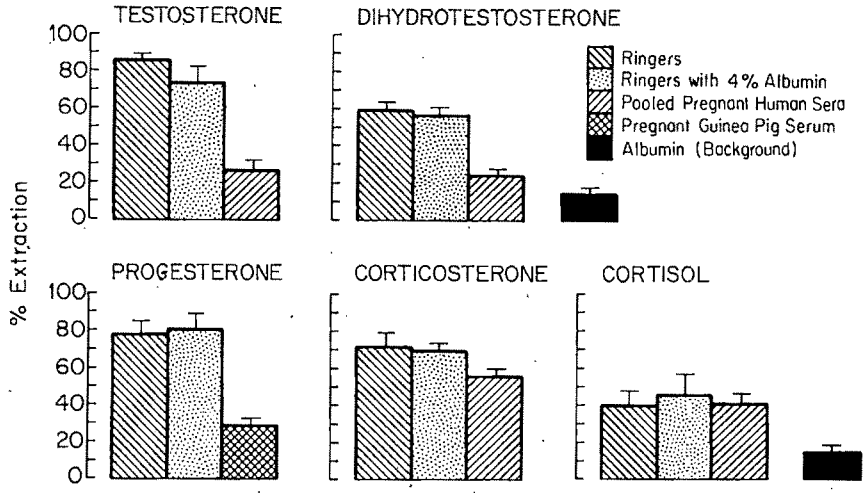

Fig. 5. The mean uterine extractions (percentage) in the rabbit of testosterone, dihydrotestosterone, progesterone, corticosterone, and cortisol relative to that of [^{14}C]butanol are shown; injection solutions contained variable amounts of serum proteins.

determined. The ratio of the dialyzable fraction before incubation to the dialyzable value after heat treatment gave the value of the percent free plus albumin bound.[11]

Statistical analysis of the results was performed with one-way analysis of variance with Duncan's range test or Student's *t* test, where appropriate.

Results

To examine the selective permeability characteristics of the microvasculature of the rabbit uterus, the E_T values of several steroids were determined with Ringer's solution containing 0.1% albumin as the injection vehicle (Fig. 3). Data are mean ± SE (three to six animals per point). The background value of albumin corresponded to the amount shown to remain in the uterine vasculature at 10 seconds. The unidirectional extractions from Ringer's lactate of labeled estrone, estradiol, and testosterone were nearly complete on a single pass through the uterus (i.e., 80%). The extractions of dihydrotestosterone, estriol, progesterone, and corticosterone ranged from 60% to 77%, while those of cortisol and estrone sulfate were reduced at 40% and 27%, respectively.

Fig. 4 shows the mean extractions of different estrogens by the uterus with different injection vehicles.

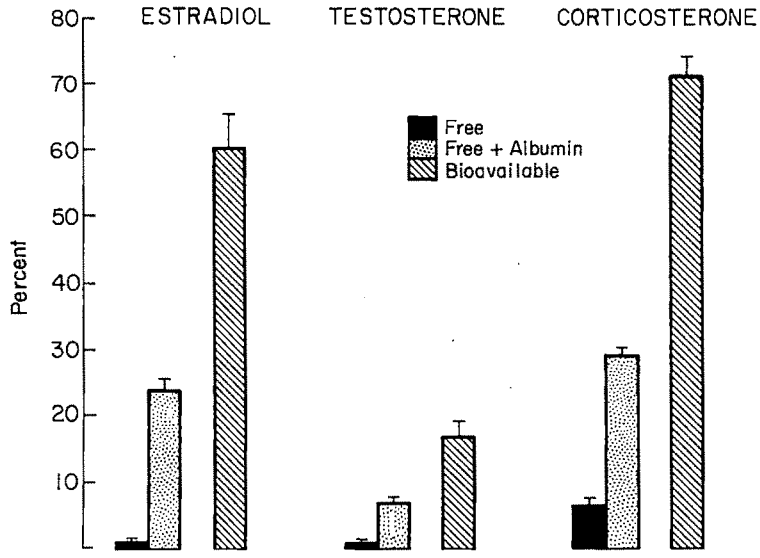

Fig. 6. The percent free (dialyzable) and free plus albumin-bound fractions of labeled estradiol, testosterone, dihydrotestosterone, and corticosterone in undiluted human pregnancy serum in vitro are shown. The fraction of total steroid hormone in human pregnancy serum available for influx into the uterus is also shown.

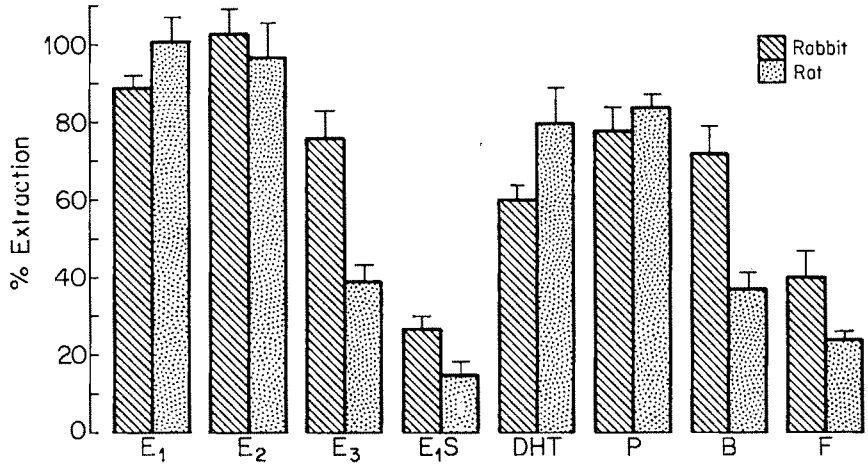

Fig. 7. A comparison between the rabbit (*hatched bars*) and rat (*stippled bars*) uterine extraction (percentage) of labeled estrone (E_1), estradiol (E_2), estriol (E_3), progesterone (P), dihydrotestosterone (DHT), corticosterone (B), cortisol (F), and estrone sulfate (E_1-S) in Ringer's solution relative to that of [^{14}C]butanol is shown. Data are the mean ± SE (three to eight naimals per point). Extraction values include background extraction represented by uptake of [^{3}H]albumin (rabbit) or [^{14}C]dextran (rat).

When albumin was added to Ringner's solution, it did not reduce the influx of estrogens in vivo. When human pregnancy serum served as the injection vehicle, it reduced the influx of estradiol ($p = 0.01$) but did not affect the influxes of estrone or estriol. The extraction of estrone sulfate was reduced to values just above background.

Fig. 5 shows the extractions of progesterone, testosterone, and dihydrotestosterone when different injection vehicles were used. The addition of 4% bovine serum albumin to Ringer's solution had no significant effect on the extractions of these steroids in vivo.[2, 12] With pregnant guinea pig serum as the injection vehicle, the extraction of progesterone was reduced ($p = 0.001$), and with the use of human pregnancy sera, the in vivo uptakes of testosterone ($p = 0.005$) and dihydrotestosterone ($p = 0.001$) were decreased. Fig. 5 also shows the extractions of corticosterone and

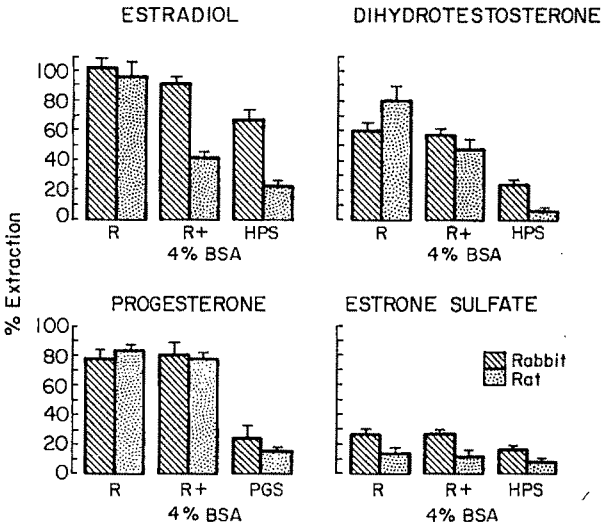

Fig. 8. A comparison between the rabbit (*hatched bars*) and rat (*stippled bars*) of the impact of plasma proteins on the mean uterine extraction of four different classes of steroids, estradiol (C_{18}), dihydrotestosterone (C_{19}), progesterone (C_{21}), and estrone sulfate (steroid conjugate) is shown. *R* = Ringer-Hepes buffer; *BSA* = bovine serum albumin; *HPS* = *human pregnancy serum; PGS* = pregnant guinea pig serum.

cortisol with different injection vehicles. Neither 4% bovine serum albumin nor human pregnancy sera exerted effects on the extractions of these steroids.

The percentages of free (dialyzable) and free plus albumin-bound fractions of labeled estradiol, testosterone, and corticosterone in human pregnancy sera measured in vitro are shown in Fig. 6. The percentages of the same steroids that were bioavailable in vivo are also shown for comparison. The bioavailable fractions of estradiol and corticosterone greatly exceeded the fractions that were free and albumin bound, while the bioavailable testosterone approximated the free plus albumin-bound fractions.

Fig. 7 shows a comparison between the mean uterine extractions of different steroids measured in rabbits and those reported earlier for rats. With the exception of dihydrotestosterone, the percentages of steroids that were bioavailable to the rabbit uterus were the same as or exceeded those injected into the uterus of the rat. However, a parallelism existed between the fractions of each steroid entering the uteri of the two species.

Fig. 8 compares the effects of plasma proteins on the mean extractions of four different classes of steroids, estradiol (C_{18}), dihydrotestosterone (C_{19}), progesterone (C_{21}), and estrone sulfate (steroid conjugate), by the rabbit uterus and the rat uterus, as reported earlier. The impact of plasma proteins on the uptake of these steroids, with the exception of estradiol, was also similar between species. In the presence of bovine serum albumin and human pregnancy serum, much greater fractions of this estrogen entered the uterus of the rabbit.

Comment

In this study, we developed a single bolus injection, double-isotope, timed tissue sampling method suitable for studies in the rabbit model. The use of this technique extended our previous work in rats[1,2] and characterized the role of microvasculature permeability barrier and the effect of plasma protein binding on the unidirectional influx of radiolabeled steroids into the rabbit tuerus. The extraction values measured in this study were *unidirectional* extractions, as opposed to *net* extractions, which are determined from arteriovenous difference measurements. Net extractions mainly reflect cellular steroid metabolism and are a complex function of metabolism, blood flow, cell membrane permeability, and plasma protein binding. Conversely, unidirectional extractions are independent of tissue metabolism of steroids and are therefore more reliable measures of membrane permeability and plasma protein–binding effects.

Marked variability in the influxes of steroids from the circulation into the uterus during a single pass was observed when Ringer's solution was used as the injection vehicle (Fig. 3). These ranged from 103% for estradiol to 27% for estrone sulfate. This differential permeability did not completely parallel the lipid solubility of these compounds as measured by the 1-octanol/Ringer's partition coefficient.[2,12] For example, the partition coefficient for estrone sulfate[2] was threefold greater than for corticosterone,[12] yet the influx of corticosterone was about threefold greater than that of estrone sulfate. The polarity of the compound, which is a function of the hydrogen bond–forming functional groups[13] and the charged functional groups, appeared to predict membrane permeability much better than the 1-octanol/Ringer's partition coefficient.[2,12] These observations were similar to those made previously with a rat uterine model.[1,2]

The addition of plasma proteins to the injection vehicle had varied inhibitory effects on the in vivo extractions of steroids by the rabbit uterus, but these could not be predicted from in vitro studies of steroid binding to plasma proteins. For example, the addition of 4% bovine serum albumin to the injection solution had no inhibitory effects on the in vivo influxes of the steroids tested, although albumin binds to these steroids in vitro.[2,12] Similar discrepancies between the impact of albumin binding of steroids as measured in vivo or in vitro have been reported for the rat uterine model.[1,2]

The presence of sex hormone–binding globulin in the injection vehicle inhibited the influxes of the sex steroids into the rabbit uterus. Greater inhibitions of

testosterone and dihydrotestosterone than of estradiol were observed when human pregnancy serum was the injection vehicle. These findings could be expected from the dissociation constants of these steroids from sex hormone–binding globulin.[14] The presence of progesterone-binding globulin in guinea pig sera also inhibited influx of progesterone into the rabbit uterus.

When the fractions of steroids in human pregnancy sera that were free and albumin bound were estimated in vitro with centrifugal ultrafiltration dialysis[10] and compared with the fractions that were bioavailable in vivo (Fig. 6), it was clear that the bioavailable fractions of estradiol and corticosterone greatly exceeded the fractions that were free and albumin bound. These large discrepancies indicated that estradiol and corticosterone were readily available for influx from the circulating sex hormone–binding globulin and human corticosteroid–binding globulin bound pools, respectively. The bioavailable fraction of circulating testosterone, 17% ± 2%, only modestly exceeded the free plus albumin-bound testosterone fraction, 7% ± 1% (Fig. 6), which indicated that testosterone was not readily available for uterine extraction from the circulating sex hormone–binding globulin bound pool.

In vitro, estrone sulfate exhibits no binding to sex hormone–binding globulin.[15] Thus, the in vivo inhibition of influx of estrone sulfate into the rabbit uterus with human serum was probably due to its binding to other plasma substances. Our observation that estrone sulfate was not available to the rabbit uterus is similar to that of other workers.[16] The influence of human sex hormone–binding globulin on the uptake of testosterone and of pregnant guinea pig sera on the uptake of progesterone into the rabbit uterus was similar to that reported earlier in rats (Fig. 8).

Although many similarities between the findings made in these two species existed, several differences were found. In general, these differences were of a quantitative nature, with the influence of capillary membrane permeability barriers and plasma protein binding on the influx of steroids being less in the rabbit than in the rat model. Of particular interest were the differences observed between species for estradiol[2] (Fig. 8). In the presence of human pregnancy serum, the fraction of this estrogen entering the rat uterus in vivo was approximately 15%,[2] which was less than the free plus albumin-bound fractions measured in vitro, i.e., 24% (Fig. 6). However, the fraction of circulating estradiol entering the rabbit uterus in vivo was 61% with the same injection vehicle. This finding raises the question whether enhanced availability of estradiol to the rabbit uterus contributes to the development of endometrial cancer in this species.

In conclusion, it was observed that the principles of hormone delivery found in rats were applicable to rabbits, as there was general parallelism between the influences of both capillary membrane permeability barriers and plasma protein binding on steroid influxes into the uteri of these two species. This parallelism suggests that the mechanisms observed in rats are not restricted to that species but may have more universal applications. Differences of in vivo uptake of circulating steroids were also observed between the species studied. These differences underscore the importance of future studies in primates to delineate more clearly steroid transport into tissues of humans.

We thank J. Wang and J. Eisenberg for their excellent technical assistance.

The effect of mild hypoxemia maintained for twenty-four hours on maternal and fetal glucose, lactate, cortisol, and arginine vasopressin in pregnant sheep at 122 to 139 days' gestation

Molly E. Towell, M.B., Jorge Figueroa, M.D., Scott Markowitz, B.A., Beth Elias, B.Sc., and Peter Nathanielsz, M.D., Ph.D.

Ithaca, New York, and Hamilton, Ontario, Canada

The effects of prolonged mild hypoxemia on the fetus have received little attention. We investigated the response to a decrease in fetal arterial Po_2 of 5 mm Hg or less sustained for a period of 24 hours in the chronically instrumented fetal lamb. Hypoxemia was induced by an infusion of nitrogen via the maternal trachea for 24 hours in 13 pregnant sheep at 122 to 139 days' gestation. Two control periods of air infusion via the maternal trachea for 24 hours were alternated with hypoxemia. Fetal hypoxemia was not associated with any change in fetal pH. During the first and second exposures to hypoxemia, there was an increase in fetal plasma lactate of 22.8 ± 22.3 and 15.3 ± 14.6 mg · dl^{-1} (mean ± SD) above preliminary values ($p < 0.05$) compared with the control period. Fetal plasma cortisol also increased by 5.7 ± 6.1 and 9.5 ± 5.4 ng · ml^{-1} (mean ± SD) ($p < 0.05$) compared with the control period. These results suggest that the fetal lamb at 122 to 139 days' gestation is highly sensitive to small decrements in Po_2 of 5 mm Hg or less. (Am J Obstet Gynecol 1987;157:1550-7.)

Key words: Fetal sheep, mild hypoxemia, Po_2, lactate, cortisol, arginine vasopressin

Fetal hypoxemia is a major cause of perinatal death and neonatal morbidity. Many studies have been conducted in pregnant ewes to investigate the effects of short-term hypoxemia for periods of up to several hours. In general, fetal hypoxemia has been induced by lowering maternal inspired oxygen concentration to 9% to 10%, which results in a reduction in fetal Po_2 of about 10 mm Hg. These studies have contributed significantly to our knowledge of the fetal response to severe hypoxemia with respect to the endocrine,[1-4] cardiovascular,[5] and respiratory systems.[6] However, little is known about the response of the fetus to prolonged mild hypoxemia.

Mild to moderate fetal hypoxemia may occur during a chronic reduction in placental blood flow in association with cyanotic heart disease in the mother or during ascent to altitude. We have also demonstrated that throughout the latter part of pregnancy, the fetus is exposed to regular reductions of Po_2 associated with uterine contractures.[7] Both spontaneous and induced myometrial contractures have been found to be associated with a decrease in fetal Po_2 and the incidence of fetal breathing.[8, 9] Similar changes have been demonstrated when fetal Po_2 was reduced by an average of 4.9 mm Hg after brief occlusions of the uterine arteries.[10] For these reasons, we felt that it was important to study the response of the fetus in late gestation to mild to moderate hypoxemia sustained over many hours.

We have developed a model in the pregnant ewe whereby small, precisely regulated degrees of fetal hypoxemia can be produced by an infusion of nitrogen into the maternal trachea.[11] The advantage of this technique is that the mother can feed and drink without interruption and is apparently unaware of low-grade changes in inspired oxygen concentration. We have now used this model to study the effects of mild fetal hypoxemia maintained for 24-hour periods in the fetal lamb.

Material and methods

Thirteen pregnant ewes were prepared for these experiments. Surgery was performed at 116 to 124 days' gestation under halothane general anesthesia. Polyvinyl catheters were placed in the maternal carotid artery, jugular vein, and trachea. The tracheal catheter (3.5

mm outer diameter and 2.5 mm inner diameter) was introduced in the direction of the lungs to a distance of 15 cm into the trachea from a point approximately 2 to 3 cm below the cricoid.[11]

Polyvinyl catheters were introduced into the fetal carotid artery, jugular vein, and amniotic cavity as previously described.[12] Electrodes of stainless steel wire (Cooner wire AS632) were also placed into the cortex of the fetal brain, the eyelids, nuchal muscle, alae nasi, or diaphragmatic muscle and subcutaneous tissue of the thorax to record fetal biophysical variables.[9] In addition, electrodes were also secured to the myometrium to record uterine activity.[9] Catheters and electrodes were exteriorized through the flank of the ewe.

Oxygen tension was measured continuously in fetal carotid arterial blood by means of a miniaturized Clark-type electrode mounted on the tip of a double-lumen catheter (venous oxygen probe, Orange Medical Instrumentation, Ltd., High Wycombe, England)[7] and in subcutaneous tissue by means of custom-made galvanic oxygen electrodes.[13] The results of continuous oxygen measurements, cardiovascular responses, and other biophysical variables will be presented in forthcoming papers.

The experimental protocol began on the fifth to seventh day after surgery and continued for a period of 4 days. On the preliminary day before the experiment, no gas was infused into the maternal trachea. On the first experimental day (day 1), compressed air was infused via the tracheal catheter at a rate of 4 or 6 L/min for a 24-hour period. On the following day, the infusion was switched to nitrogen at 4 or 6 L/min to lower maternal alveolar P_{O_2}. The air and nitrogen infusions were repeated on the third and fourth experimental days, respectively.

Arterial blood samples were obtained from both mother and fetus on the preliminary day before the experimental protocol was begun and thereafter at

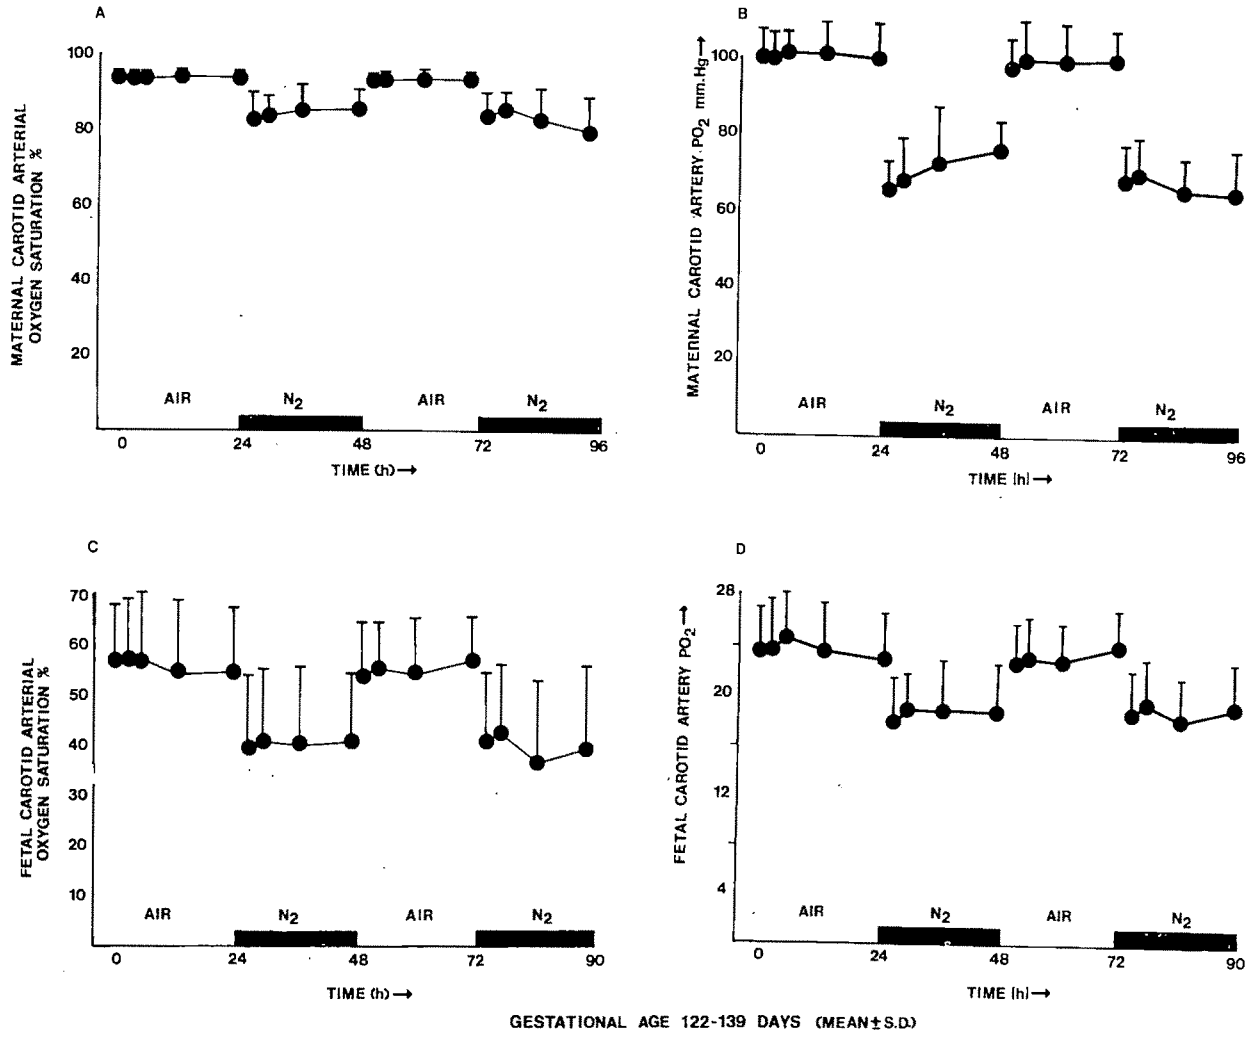

Fig. 1. Maternal arterial oxygen saturation (**A**) and oxygen tension (**B**) and fetal arterial oxygen saturation (**C**) and oxygen tension (**D**) in 16 experiments at 122 to 139 days' gestation (mean ± SD). Nitrogen was infused at 4 or 6 L · min^{-1} via a tracheal catheter in the ewe to produce hypoxemia (■). On control days, air was infused at 4 or 6 ml · min^{-1}.

2, 4, 12, and 23 hours on each day of air or nitrogen infusion. Heparinized blood samples (1 ml) were obtained for measurement of pH, blood gases, oxygen saturation, hemoglobin, and whole blood glucose. Additional samples (1.5 ml) were obtained for measurement of plasma lactate, cortisol, and arginine vasopressin. Fetal red cells were returned to the fetus after centrifugation of the sample and separation of plasma.

The pH and blood gases were measured by means of a Radiometer BMS3 maintained at a temperature of 39° C. Oxygen saturation and hemoglobin were measured with a Radiometer OSM2 hemoximeter. Whole blood glucose and plasma lactate were measured by specific enzymatic techniques with a Yellow Springs Instrumentation analyzer (Model no. 27). Cortisol was measured with a specific radioimmunoassay after methylene dichloride extraction; this method has been validated for measurement of cortisol in fetal and maternal plasma.[14]

Arginine vasopressin in fetal and maternal plasma was measured with a radioimmunoassay after acetone-petroleum ether extraction of plasma. Cold acetone (2 ml) was added to 0.6 ml of plasma, mixed on a multiple tube vortex for 1 minute, and centrifuged at 4000 rpm at 4° C for 20 minutes. The supernatant was decanted into a tube containing 2 ml of petroleum ether, mixed, and allowed to stand for 10 minutes before freezing the aqueous (lower) phase at −60° C in methyl alcohol. The organic phase was poured off, and the aqueous phase, which contains arginine vasopressin, was dried overnight by lyophilization. The extract was resuspended in 1 ml assay buffer (0.02 mol/L of 5,5-diethylbarbituric acid, 0.139 mol/L of sodium chloride, 0.011 mol/L of sodium ethylenediaminetetraacetic

acid, 0.066 mmol/L of L-cystine, and 0.25% of bovine serum albumin (pH 7.4), and 0.45 ml of the reconstituted extract was measured in duplicate in the assay.

Standard curves were prepared by mixing unlabeled arginine vasopressin (Bachem, Torrance, Calif.), which ranged from 0.06 to 8.0 pg in 0.45 ml buffer per tube, and 50 μl of antibody (the Arnel Products Co., New York, N.Y.) to a final dilution of 1:125,000 in a volume of 0.55 ml. After 24-hour incubation at 4° C, 2000 cpm of iodine 125–arginine vasopressin (NEX-128; 2200 Ci/mmol, New England Nuclear, Boston, Mass.) in 50 μl was added, which was followed by further incubation for 48 hours at 4° C. Separation of free iodine 125–arginine vasopressin was carried out after the addition of 200 μl, 2.0% charcoal, 0.75% dextran in 0.1 mol/L of phosphate buffer, pH 7.4, and centrifugation at 4000 rpm. Precipitates containing unbound arginine vasopressin were counted in a Micromedics γ-counter for 5 minutes. Extraction efficiency (70%) was evaluated by extraction of 2 and 4 pg of cold arginine vasopressin from low pool plasma. Maternal and fetal plasma extracts diluted in parallel to the standard curve. Antisera cross-reactivity was <0.01% with oxytocin, 15% with lysine vasopressin, and 31% with arginine vasotocin. Sensitivity of the assay was 0.1 pg per tube. Intra-assay coefficient of variation was 9.4% and interassay coefficient of variation was 12.1%.

Statistical analysis. Gestation at the start of the experiment ranged from 122 to 136 days. Sixteen experiments were performed in 13 ewes; three ewes were subjected to a second experiment 7 to 14 days later. The infusion rate of air or nitrogen via the maternal trachea was set at 4 L/min in nine experiments and 6 L/min in the other seven experiments. All plasma samples were not analyzed for all hormones and metabolites. The number of samples assayed for each variable depended on availability of plasma. For the purpose of statistical analysis, all results available from the 16 experiments have been pooled since there were no significant differences between infusion rates of 4 L of nitrogen and 6 L nitrogen per minute.

Increments from preliminary values on the different days of air or nitrogen infusion were calculated with the use of mean values for the four samples obtained on each day. Initial one-way analysis of variance was performed on the data, followed by the paired t test with Bonferroni correction on the increments from the preliminary values on the different days. The mean ± SD for the increment above the preliminary day on each day was calculated. The paired t test was used to test whether the increment on each day of nitrogen administration was significantly different from zero. Thus two comparisons were made (i.e., the increment on days 2 and 4 were significant). Significance was assumed at $p < 0.05$ (equivalent to 0.025 after Bonferroni correction). To analyze the speed of any changes, the last sample obtained while the trachea was infused with compressed air was compared with the first sample (after 2 hours) of nitrogen infusion on both days 2 and 4 with use of the paired t test. Significance was assessed at the 0.05 level. Unless otherwise stated, data are presented throughout as mean ± SD.

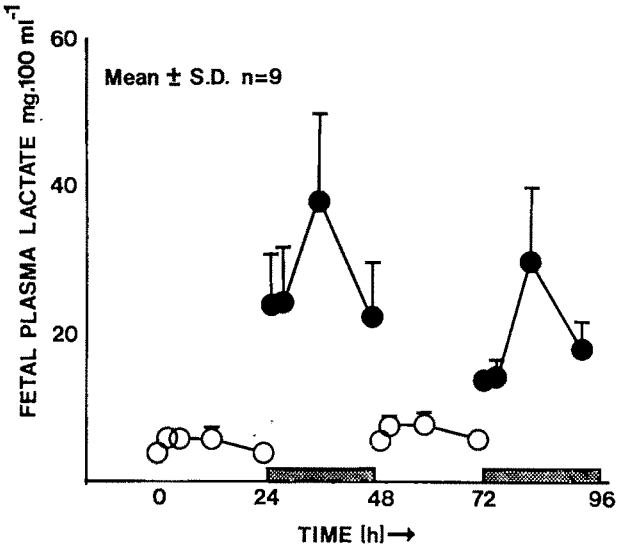

Fig. 2. Fetal plasma lactate in the fetuses of nine ewes at 122 to 132 days' gestation. Air (○) or nitrogen (●) was infused into the maternal trachea at 4 or 6 L · min^{-1}. *Bars* (▬) indicate 24-hour periods of hypoxemia.

Results

Outcome of experiments. One fetus died on the fourth day during nitrogen infusion. The mother had shown increasing uterine activity during the experiment and was in labor at the time of fetal death. All other fetuses survived the experimental period. In one experiment, the ewe showed signs of increasing respiratory distress during nitrogen infusion, which was therefore discontinued approximately 12 hours before the end of the fourth day's protocol. In one other experiment, the nitrogen infusion was accidently disconnected during the last 12 hours of infusion on day 4. The results of blood samples obtained during these periods have therefore been excluded from the final analysis.

Changes in fetal and maternal pH, blood gases, and hemoglobin. The absolute values for the fetal and maternal variables averaged for the preliminary day and the increments for each day of the experimental period are shown in Tables I and II. Both maternal and fetal arterial P_{O_2} and oxygen saturation decreased significantly on days 2 and 4 during nitrogen infusion. There was no significant change in maternal and fetal pH or hemoglobin. Maternal and fetal P_{CO_2} decreased on

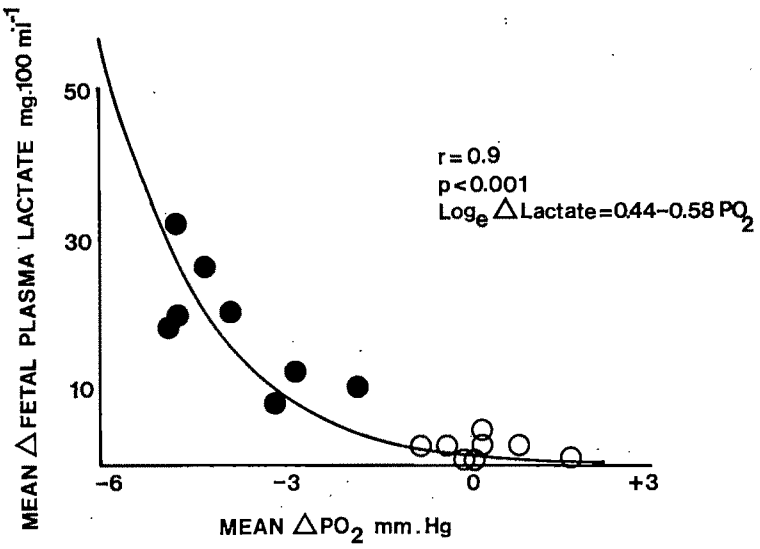

Fig. 3. Relationship between change in mean plasma lactate and change in mean PO_2 in fetal carotid arterial blood compared with preliminary day when no gas was infused. *Open circles* (○) indicate samples obtained during infusion of air, and *closed circles* (●) indicate samples obtained during infusion of nitrogen via a maternal tracheal catheter. Mean values for all fetuses at each of the 16 data points on days 1 to 4 are shown.

days 2 and 4 during nitrogen infusion. Hypocarbia was almost certainly caused by maternal hyperventilation as a result of hypoxemia.

Fig. 1 illustrates the changes in PO_2 and oxygen saturation (mean ± SD) in maternal and fetal blood for all 17 samples obtained during the 5-day experimental protocol. It can be seen that the decrease in maternal arterial PO_2 of about 30 to 35 mm Hg was accompanied by only a small decrease in oxygen saturation of <10%. On the other hand, in the fetus, the decrease in PO_2 was only about 5 mm Hg, but was accompanied by a larger decrease in oxygen saturation than in the mother, that is, about 15%.

Fetal and maternal blood glucose and plasma lactate. Fetal and maternal blood glucose values did not vary significantly on any of the experimental days. However, fetal plasma lactate was significantly elevated on days 2 and 4 during nitrogen infusion. Maternal plasma lactate values showed little change except for day 4 when the small increase in lactate achieved statistical significance (Table II). The fetal lactate values for each of the 17 samples obtained during the 4-day protocol are shown in Fig. 2. It can be seen that fetal plasma lactate values had increased more than twofold within 2 hours ($p < 0.05$) of the start of nitrogen infusion, peaking at greater than 12 hours and tending to decrease toward normal at greater than 23 hours.

The relationship of mean ΔPO_2 to mean Δ lactate values in the fetus for all 16 samples during the experimental period is shown in Fig. 3. Fetal lactate values increase significantly as a function of decreasing PO_2. The exponential best fit equation shows that fetal plasma lactate rose 2.8 $mg \cdot dl^{-1}$ when the PO_2 fell 2 mm Hg. The rise in fetal plasma lactate was 21 $mg \cdot dl^{-1}$, for a 5 mm Hg fall in PO_2.

Fetal and maternal plasma cortisol. Concentrations of fetal plasma cortisol increased significantly on days 2 and 4 during nitrogen infusion ($p < 0.05$), but no significant changes occurred in maternal cortisol values (Tables I and II). Plasma cortisol values for both mother and fetus (mean ± SEM) in all 17 samples obtained during the 4-day protocol are shown in Fig. 4. It can be seen that there was wide variation in both vascular compartments, particularly in the mother. However, in the fetus, the increase in plasma cortisol was more consistently related to the onset of hypoxemia and was statistically significantly elevated by 2 hours on days 2 and 4 ($p < 0.05$).

Fetal and maternal arginine vasopressin. No changes were observed in either maternal or fetal arginine vasopressin values during the 4 day protocol (Tables I and II).

Comment

Most studies on the effect of hypoxemia on the fetus have been relatively short-term, that is, in the order of hours rather than days. Furthermore, in most studies fairly severe maternal and fetal hypoxemia has been induced by reducing maternal inspired oxygen concentration to about 50% of normal. Under these con-

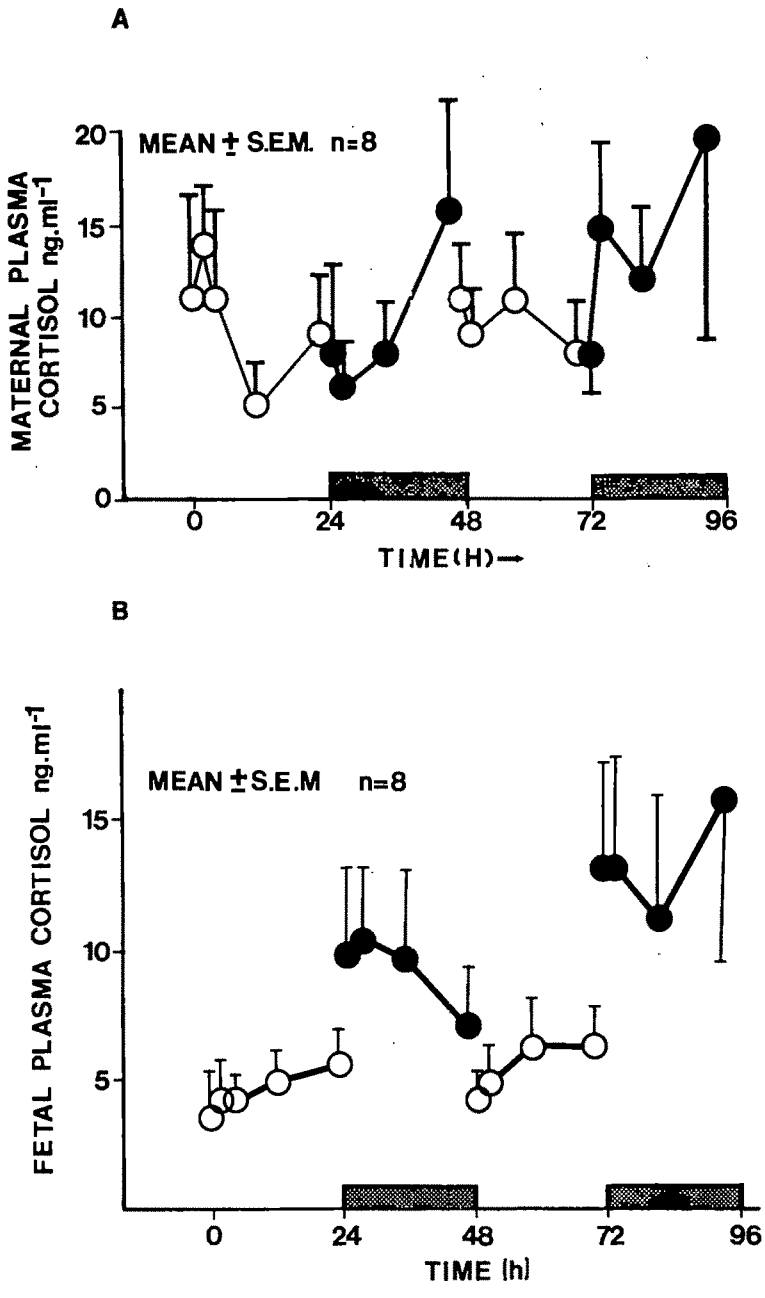

Fig. 4. Maternal arterial plasma cortisol concentration (**A**) and fetal carotid arterial plasma cortisol concentration (**B**) in eight experiments at 122 to 139 days' gestation. *Open circles* (○) indicate samples obtained during infusion of air and *closed circles* (●) during infusion of nitrogen to produce hypoxemia (▬).

ditions, fetal P_{O_2} falls by 50%, and fetal acidosis develops to varying degrees, depending on the duration of hypoxemia.

Our experiments were directed toward obtaining an understanding of how well the fetus tolerates prolonged mild hypoxemia. We considered this to be important from the following points of view: (1) The fetus undergoes multiple episodes of mild hypoxemia with drops in arterial P_{O_2} of 2 to 8 mm Hg at regular intervals during late gestation in association with uterine contractures; (2) the ascent to altitude during pregnancy is associated with mild maternal-fetal hypoxemia depending on the level of ascent, and (3) persistent mild-to-moderate hypoxemia is believed to occur in association with intrauterine growth failure in the clinical situation.

Our data show that prolonged mild fetal hypoxemia resulting from maternal hypoxemia was well tolerated by the fetus but leads to significant metabolic responses by the fetus or the placenta that were not observed in the mother. Fetal plasma lactate increased significantly. It appears that hypoxemia induced by lowering inspired P_{O_2} in the mother is tolerated better by the mother than by the fetus. This is not altogether surprising in view of the difference in maternal and fetal oxygen dissociation curves. A decline in P_{O_2} of 35 mm Hg in the mother led to a decrease in oxygen saturation of <10%, whereas a decline of only 5 mm Hg in the fetus led to a decrease in oxygen saturation of 15% or more. This represents a percentage change of nearly 30% in the fetus compared with only 10% in the mother. Oxygen availability to tissues depends on the amount of oxygen carried by hemoglobin and the P_{O_2} gradient from plasma to tissues. It is apparent that the reduction in fetal oxygen availability in our experiments was sufficient to cause tissue oxygen deprivation and metabolic effects in the fetus. We do not have any data to show where the lactate that appeared in fetal plasma was being produced, but it is possible that a decrease in blood flow to fetal muscles and other organs in response to mild hypoxemia was sufficient to trigger anaerobic metabolism and lactate production. The possibility that placental lactate production is altered by small changes in P_{O_2} or oxygen content is an intriguing one that should be investigated.

There was no significant change in fetal pH during hypoxemic periods despite a significant change in fetal lactate. This was probably accounted for by a reduction in P_{O_2} in both maternal and fetal compartments caused by maternal hyperventilation.

Significant changes were observed in cortisol concentrations of both maternal and fetal plasma during the hypoxemic episodes. This increase was significant in fetal plasma within 2 hours of the start of the hypoxemia. However, perusal of the data presented in Fig. 4 shows that there was wide variation in the cortisol response, particularly in the maternal compartment. Cortisol has been shown to cross the placenta in both directions, and it is possible that in certain situations, fetal values could be a reflection of those in the mother. However, placental transfer does not usually occur unless maternal cortisol values exceed 44 ng · ml^{-1}.[15] Maternal cortisol in our ewes rarely exceeded these values, and fetal values increased within 2 hours of the first exposure to hypoxemia at a time when maternal values were not increased (Fig. 4).

The plasma cortisol values found in both mother and fetus during hypoxemic episodes were considerably lower than those reported by other investigators during hypoxic episodes in the ewe. Boddy et al.[1] exposed pregnant ewes to 9% oxygen. Their increase in maternal plasma cortisol ranged from 18.7 to 145 ng · ml^{-1} and from 10.7 to 30.4 ng · ml^{-1} in fetal plasma cortisol. They also observed that maternal adrenocorticotropic hormone increased about 2.5-fold during hypoxemia, whereas fetal adrenocorticotropic hormone increased about 14-fold. The effect of progressive fetal hypoxemia and acidosis induced by administration of a hypoxic gas mixture (9% oxygen) to the pregnant ewe over a period of 7.2 hours was also studied by Challis et al.[4] In contrast to Boddy et al.,[1] they found little change in maternal adrenocorticotropic hormone or cortisol levels, but a large increase in fetal adrenocorticotropic hormone and cortisol values occurred within 3 hours of sustained hypoxemia.

Our observations suggest that the fetal pituitary adrenal axis at 122 to 139 days' gestation is quite sensitive and responds to mild hypoxemia (ΔP_{O_2} of -5 mm Hg) by releasing cortisol. We cannot entirely exclude some transplacental contribution from the maternal compartment, but as previously mentioned, this is unlikely. Other investigators[16] have shown that the direction of transfer of cortisol across the placenta is more likely to be from fetus to mother than in the reverse direction. The modest increase in fetal cortisol values, that is, about twofold, in our experiments is higher than that observed with moderate fetal hypoxemia induced by a reduction in uterine blood flow for 2 hours.[3] In the latter experiments, mean fetal cortisol values increased by 1.3 times for all gestational ages combined, but the largest increase (>200%) was observed in fetuses of 120 to 138 days. All but one of our fetuses fell into this gestational age range, which may help explain the apparent sensitivity of the fetal adrenal gland observed in our experiments. Finally, arginine vasopressin values were not increased in either mother or fetus, suggesting that the posterior pituitary gland is not sensitive to mild reductions in fetal P_{O_2} of this magnitude.

We thank Robin Poore for helpful discussions and assistance with the conduct of this study, Jean Johnson, Gabriela Pimentel, and Tuan Dinh for technical assistance, and Karen Moore for help with the manuscript and the illustrations.

Fetal heart rate response to vibratory acoustic stimulation predicts fetal pH in labor

Terri G. Edersheim, M.D., J. Milton Hutson, M.D., Maurice L. Druzin, M.D., and Elizabeth A. Kogut, R.N.C.

New York, New York

Vibratory acoustic stimulation was performed during labor in 188 instances 60 seconds before fetal scalp puncture was done to determine fetal scalp blood pH. The fetal heart rate response was recorded for both vibratory acoustic stimulation and fetal scalp puncture. No instance of fetal acidosis occurred in the presence of an acceleration to either vibratory acoustic stimulation or fetal scalp puncture. Vibratory acoustic stimulation was more likely to elicit an acceleration than fetal scalp puncture in the nonacidotic fetus. Vibratory acoustic stimulation is less invasive and may be used in some instances in which fetal scalp blood puncture for pH determination is technically impossible. (AM J OBSTET GYNECOL 1987;157:1557-60.)

Key words: Vibratory acoustic stimulation, fetal pH, fetal heart rate monitoring

Accelerations in fetal heart rate induced by vibratory acoustic stimulation of the fetus have been associated with fetal well-being during both the antepartum and intrapartum periods.[1-4] The increase in heart rate observed is thought to be related to a change in the state of arousal, which is manifested in a startle response of the fetus similar to that observed in the neonate.[5,6] Loss of the startle reflex in the neonate may indicate altered neurologic function or acidosis. Direct fetal scalp stimulation that results in an acceleration in heart rate has also been correlated with a normal acid-base status.[7] This study was undertaken to examine the relationship between vibratory acoustic stimulation, direct fetal scalp stimulation, and fetal scalp blood pH.

Table I. Indications for fetal pH determination

Indication	*No. of samples*
Late decelerations	96
Severe variable decelerations	52
Bradycardia	34
Tachycardia	25
Decreased variability	13
Meconium	5
Sinusoidal pattern	2
Saltatory pattern	2

Material and methods

This study was undertaken at The New York Hospital–Cornell University Medical College from March 1985 to March 1986. All patients included were in active labor with ruptured membranes and had evidence of abnormal fetal heart rate tracings. Liberal guidelines for performing fetal pH determinations are used on our service; those patients with suspicious or equivocal tracings have a pH measurement obtained. In addition, any patient with meconium plus a fetal heart rate abnormality such as decreased beat-to-beat variability or fetal tachycardia had a fetal scalp blood pH measurement performed. All patients were 34 weeks' gestation or greater. The fetal heart rate was monitored continuously by means of the Corometrics 112 fetal heart rate monitor. Sixty seconds before determination of scalp blood pH, a single 3-second vibratory acoustic stimulus was applied over the fetal vertex with the use of the Western Electric Model 5c electronic artificial larnyx. Fetal heart rate was observed for 60 seconds and fetal scalp blood was then obtained by the standard puncture technique and analyzed on a Corometrics 220 pH system. Fetal heart rate response to both vibratory acoustic stimulation and fetal scalp stimulation was recorded and correlated with the pH value obtained. An acceleration was defined as an increase in fetal heart rate above the baseline of 15 bpm sustained for 15 seconds occurring within 60 seconds after either stimulation.

Results

Fetal heart rate response to both vibratory acoustic stimulation and fetal scalp stimulation was recorded in 183 instances in 127 patients. Typical fetal heart rate recordings in both nonacidotic and acidotic fetuses are shown in Figs. 1 and 2. The indications for fetal pH determination are listed in Table I, with more than one indication present in some patients. Fetal bradycardia was defined as a decrease in fetal heart rate of >30 bpm lasting for more than 60 seconds that had resolved before the pH determination. Table II lists the accel-

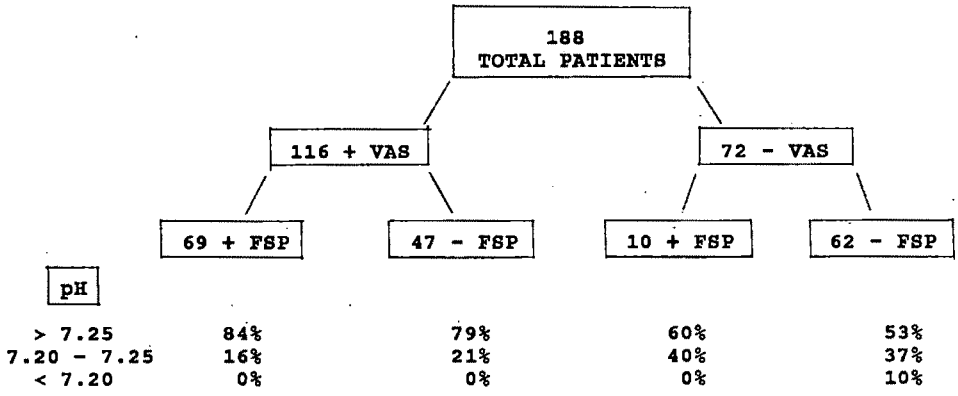

Fig. 3. The incidence of acceleration (+) and no acceleration (−) to vibratory acoustic stimulation *(VAS)* and subsequent fetal scalp puncture *(FSP)* divided by fetal scalp blood pH.

Table II. Response of fetal heart rate to fetal stimulation according to fetal pH

	Vibratory acoustic stimulation		*Fetal scalp puncture*	
Fetal pH	*Acceleration (%)*	*No acceleration (%)*	*Acceleration (%)*	*No acceleration (%)*
>7.25	95 (70.9)	39 (29.1)	64 (47.8)	70 (52.2)*
7.20-7.25	21 (43.7)	27 (56.3)	15 (31.2)	33 (68.8)
<7.20	0	6 (100)	0	6 (100)

*$p < 0.001$.

eration response to each stimulus according to the pH value obtained from the fetal blood sample. Fig. 3 shows the percentage of patients responding to each stimulus and the pH values of each group. No instances of fetal acidosis (pH < 7.20) occurred in the presence of an acceleration in fetal heart rate to either vibratory acoustic stimulation or fetal scalp stimulation. Vibratory acoustic stimulation was more likely to elicit an acceleration than was fetal scalp stimulation in the nonacidotic fetus (pH > 7.25).

A fetal heart rate acceleration to vibratory acoustic stimulation has a sensitivity of 63.7% and a specificity of 100% in identifying the fetus with a pH >7.20. The predictive value of a positive test (acceleration with the stimulus) was also 100%, but the predictive value of a negative test (no acceleration with the stimulus) was 8.3%. Similarly, for fetal scalp stimulation, the sensitivity was 43.4%, specificity was 100%, predictive value of a positive test was 100%, and the predictive value of a negative test was 5.5%.

The 39 instances of absent acceleration in response to vibratory acoustic stimulation with a pH >7.25 were examined. There were no differences in gestational age, presence of meconium, indications for fetal pH determination, and variable deceleration occurring with the stimulus compared with the group that responded with an acceleration. Narcotic administration had occurred within 2 hours in 23% of the no acceleration group compared with 10.5% in the acceleration group. This difference was not statistically different.

Comment

The value of fetal vibratory acoustic stimulation during the antepartum period has been previously established. The response to acoustic stimulation has been demonstrated as early as 24 weeks' gestation when studied serially from 12 to 32 weeks.[8] After 28 weeks, an invariant response to acoustic stimulation was noted with notable exceptions. The exceptions noted were in babies with congenital deafness, multiple congenital anomalies, or severe fetal compromise. It has been demonstrated that the normal startle reflex is elicited in response to vibratory acoustic stimulation both in utero and after birth. This reflex indicates an intact nervous system and may change with altered fetal sleep-wake cycles. Vibratory acoustic stimulation has been demonstrated to alter the fetal state of arousal. In this way, vibratory acoustic stimulation has been used to decrease the false-positive rate on the nonstress test by distinguishing between those fetuses who are in a sleep cycle from those who are nonreactive because of fetal compromise.[9, 10]

The value of vibratory acoustic stimulation in the intrapartum period is not as well studied as in the antepartum period.[4, 11] Fetal stimulation to assess acid-base status is not a new concept. This has been done by Clark

et al. by direct tactile scalp stimulation to alter the fetal arousal state. Vibratory acoustic stimulation is better than direct scalp stimulation in that it is less invasive than scalp puncture for pH determination or scalp stimulation alone. The safety of vibratory acoustic stimulation has been addressed by several investigators.[1, 12, 13] Thus far no untoward effects have been noted. Our study assesses the validity of the use of vibratory acoustic stimulation as a predictor of acid-base status in labor.

The specificity of an acceleration in response to vibratory acoustic stimulation is 100% in the nonacidotic fetus. The absence of an acceleration may not indicate fetal compromise, but rather may be caused by an altered state of arousal in the fetus. Although not statistically significant, a higher incidence of patients who received meperidine within 2 hours of stimulation was noted in the group that had no acceleration with a pH >7.25. The larger number of patients studied may partially explain the lack of acceleration in a nonacidotic fetus.

Electronic fetal heart rate monitoring and fetal scalp blood sampling for pH determination are the accepted methods for intrapartum fetal surveillance. Both of these methods have limitations. Fetal heart rate monitoring is complicated by a high false-positive rate.[14, 15] Our study suggests a clinical role for vibratory acoustic stimulation as a noninvasive screening tool for patients with a question of fetal compromise. This proposed approach would be as follows: (1) vibratory acoustic stimulation in the face of abnormal electronic fetal heart rate monitoring, (2) if an acceleration occurs in response to vibratory acoustic stimulation, electronic fetal heart rate monitoring should be continued, and (3) if no acceleration occurs in response to the stimulus, fetal scalp blood pH determination should be performed. Delivery should be considered in those instances of an abnormal fetal heart rate tracing with no response to vibratory acoustic stimulation and an inability to perform a fetal scalp blood pH. This approach could substantially decrease the number of scalp blood pH determinations required while still improving the specificity of electronic fetal heart rate monitoring. Another benefit of vibratory acoustic stimulation is its use in situations in which direct electronic fetal heart rate monitoring or fetal acid-base determination is not technically feasible or contraindicated, such as intact membranes, an unengaged vertex, or lack of cervical dilation.

11th Annual Gold Coast OB/GYN Conference, "Current Clinical Concepts in Reproductive Endocrinology and Perinatology," February 8-10, 1988, Good Samaritan Hospital, West Palm Beach, Florida. For more information contact: Laura Lyons, CME Coordinator, Good Samaritan Hospital, P. O. Box 3166, West Palm Beach, FL 33402. Tel.: (305) 650-6236.

High-Risk Obstetrics, March 24-26, 1988, Chicago, Illinois. Sponsored by Cook County Graduate School of Medicine. For additional information, contact the Registrar's Office. Toll-free number: In Illinois 1 (800) 621-4649; outside Illinois 1 (800) 621-4651.

Specialty Review in Obstetrics and Gynecology, April 18-23, 1988, Chicago, Illinois. Sponsored by Cook County Graduate School of Medicine. For additional information, contact the Registrar's Office. Toll-free number: In Illinois 1 (800) 621-4649; outside Illinois 1 (800) 621-4651.

The Berlex Foundation announces awards to support reproductive research. A major new program to foster medical research advances in fertility and contraception has been established by The Berlex Foundation. The program involves three graduate medical education awards for residents, scholars, and researchers in obstetrics and gynecology: the Berlex Resident Education Award, the Berlex Scholar Award, and the Berlex International Research Fellowship. For further information about The Berlex Foundation and awards criteria and applications, interested physicians should write to: The Berlex Foundation, 530 Fifth Ave., New York, NY 10036.

Bound volumes available to subscribers

Bound volumes of the AMERICAN JOURNAL OF OBSTETRICS AND GYNECOLOGY are available to subscribers (only) for the 1987 issues from the Publisher, at a cost of $51.00 ($74.00 international) for Vol. 156 (January-June) and Vol. 157 (July-December). Shipping charges are included. Each bound volume contains a subject and author index and all advertising is removed. Copies are shipped within 60 days after publication of the last issue in the volume. The binding is durable buckram with the JOURNAL name, volume number, and year stamped in gold on the spine. *Payment must accompany all orders.* Contact The C. V. Mosby Company, Circulation Department, 11830 Westline Industrial Drive, St. Louis, Missouri 63146, USA; phone (800) 325-4177, ext. 351.

Subscriptions must be in force to qualify. Bound volumes are not available in place of a regular JOURNAL subscription.

Subject index*

A

Abdomen, acute
Acute abdomen caused by placenta percreta in the second trimester (Archer and Furlong). 1987;157:146-7

Abdominal circumference
Fetal weight estimation formulas with head, abdominal, femur, and thigh circumference measurements (Vintzileos et al). 1987;157:410-4
Ultrasonic ratio of fetal thoracic to abdominal circumference: an association with fetal pulmonary hypoplasia (Johnson et al). 1987;157:764-9

Abdominal hysterectomy
Single-dose prophylaxis for vaginal and abdominal hysterectomy (Hemsell et al). 1987;157:498-501

Abdominal pregnancy
Abdominal pregnancy: magnetic resonance identification with ultrasonographic follow-up of placental involution (Spanta et al). 1987;157:887-9

Abortion
Femininity—a problem(?) (Eichner) (Letter). 1987;157:517
First-trimester vaginal bleeding and the loss of chromosomally normal and abnormal conceptions (Strobino and Pantel-Silverman). 1987;157:1150-4
Haemophilus influenzae infection and midtrimester abortion (Amstey and Ogden) (Letter). 1987;157:518
Lymphocyte-reactive antibodies and recurrent early pregnancy failure (Biddle et al) (Letter). 1987;157:785-6
Morality of induced abortion and freedom of choice (Fribourg) (Letter); (Hill) (Reply). 1987;157:215
Recurrent spontaneous abortion and human leukocyte antigen DRw8 (Takamizawa et al) (Letter). 1987;157:514-5

Abruptio placentae
Ultrasound diagnosis of abruptio placentae with fetomaternal hemorrhage (Cardwell). 1987;157:358-9

Acetaldehyde
Disposition of acute, multiple-dose ethanol in the near-term pregnant ewe (Brien et al). 1987;157:204-11

N-Acetyl-β-D-glucosaminidase
Increased tubular enzyme excretion in preeclampsia (Goren et al). 1987;157:906-8

Acid-base balance; *see also* **Acidosis**
Cord sampling for the evaluation of oxygenation and acid-base balance in human growth-retarded fetuses (Pardi et al). 1987;157:1221-8
Effects of maternal glucose infusion on fetal acid-base status in human pregnancy (Philipson et al). 1987;157:866-73
Indicators of perinatal asphyxia (Hollander et al). 1987;157:839-42

Acidosis; *see also* **Acid-base balance**
The relationships among the fetal biophysical profile, umbilical cord pH, and Apgar scores (Vintzileos et al). 1987;157:627-31
Umbilical cord blood pH and Apgar score as an index of neonatal health (Josten et al). 1987;157:843-8

Acoustic stimulation
Antepartum fetal surveillance in the patient with decreased fetal movement (Ahn et al). 1987;157:860-4
Fetal auditory brain stem response: effect of increasing stimulus rate during functional auditory development (Plessinger and Woods). 1987;157:1382-7
Fetal heart rate response to vibratory acoustic stimulation predicts fetal pH in labor (Edersheim et al). 1987;157:1557-60
Human fetal responses to vibratory acoustic stimulation from twenty-six weeks to term (Gagnon et al). 1987;157:1375-81
Intrapartum vibratory acoustic stimulation of the human fetus during episodes of decreased heart rate variability (Divon et al). 1987;157:1355-8
Neonatal auditory acuity following in utero vibratory acoustic stimulation (Ohel et al). 1987;157:440-1

Acquired immunodeficiency syndrome
Isolation of acquired immunodeficiency syndrome virus from the placenta (Hill et al). 1987;157:10-1

Actin-myosin interaction
A new look at uterine muscle contraction (Carsten and Miller). 1987;157:1303-15 (Curr. dev.)

Acute abdomen
Acute abdomen caused by placenta percreta in the second trimester (Archer and Furlong). 1987;157:146-7

Adenocarcinoma
The anatomic distribution of cervical adenocarcinoma in situ: implications for treatment (Bertrand et al). 1987;157:21-5
Endometrial adenocarcinoma estrogen receptor content: association of clinicopathologic features with immunohistochemical analysis compared with standard biochemical methods (Mutch et al). 1987;157:924-31
Endometrial metaplasia associated with endometrial adenocarcinoma (Andersen et al). 1987;157:597-604

Adenomatoid malformation
Successful fetal therapy for cystic adenomatoid malformation associated with second-trimester hydrops (Clark et al). 1987;157:294-5

Adenosine monophosphate
Changes in cyclic adenosine monophosphate–phosphodiesterase activity in nonpregnant and pregnant human myometrium (Kofinas et al). 1987;157:733-8

Adenosquamous carcinoma
Adenosquamous carcinoma of the fallopian tube: a clinicopathologic case report with verification of the diagnosis by immunohistochemical and ultrastructural studies (Moore et al). 1987;157:903-5

*July, 1-228; August, 229-520; September, 521-788; October, part 1, 789-1018; part 2, 1019-1092; November, 1093-1324; December, 1325-1618.

Adhesion
Prevention of pelvic adhesion formation by different modalities of treatment (Fayez and Schneider). 1987;157:1184-8
Adnexal cyst
Serum CA-125 in the evaluation of benign adnexal cysts (Pittaway et al). 1987;157:1426-8
Adolescence
Correlation between chlamydia infection and clinical evaluation, vaginal wet smear, and cervical swab test in female adolescents (Thejls et al). 1987;157:974-6
Teen pregnancies (Roush) (Letter); (Hollingsworth) (Reply). 1987;157:1011
The use and limitations of endocervical Gram stains and mucopurulent cervicitis as predictors for *Chlamydia trachomatis* in female adolescents (Moscicki et al). 1987;157:65-71
β-Adrenergic receptor agonist
β-Adrenergic receptor agonist infusion increases plasma prostaglandin F levels in pregnant sheep (Casper and Lye). 1987;157:998-1003
Aerobic conditioning
Effects of aerobic and strength conditioning on pregnancy outcomes (Hall and Kaufmann). 1987;157:1199-203
Age factors
Menstrual and reproductive factors and the risk of myocardial infarction in women under fifty-five years of age (La Vecchia et al). 1987;157:1108-12
Patterns of human fetal heart rate accelerations from 26 weeks to term (Gagnon et al). 1987;157:743-8
Pregnancy outcome in medically complicated and uncomplicated patients aged 40 years or older (Lehmann and Chism). 1987;157:738-42
Aging
Age-related changes in the female hormonal environment during reproductive life (Musey et al). 1987;157:312-7
AIDS; *see* **Acquired immunodeficiency syndrome**
Alanine aminopeptidase
Increased tubular enzyme excretion in preeclampsia (Goren et al). 1987;157:906-8
Alcohol; *see also* **Ethanol**
Cerebral oxidative metabolism in fetal sheep with multiple-dose ethanol infusion (Richardson et al). 1987;157:1496-502
γ-Glutamyl transferase and mean cell volume reveal maternal alcohol abuse and fetal alcohol effects (Ylikorkala et al). 1987;157:344-8
Stereotypic behavioral response of rat fetuses to acute hypoxia is altered by maternal alcohol consumption (Smotherman and Robinson). 1987;157:982-6
Ambulation
The effects of maternal ambulation on the nonstress test (Devoe et al). 1987;157:240-4
The American Board of Obstetrics and Gynecology
Approved fellowship training programs in obstetrics and gynecology subspecialties; Gynecologic Oncology; Reproductive Endocrinology; Maternal-Fetal Medicine. 1987;157:30A-5A
New certifications: subspecialty of Basic. 1987;157:218-24
New certifications: subspecialty of Gynecologic Oncology. 1987;157:226
New certifications: subspecialty of Maternal-Fetal Medicine. 1987;157:224-5
New certifications: subspecialty of Reproductive Endocrinology. 1987;157:225-6
Aminophylline
The effects of aminophylline and nifedipine on contractility of isolated pregnant human myometrium (Bird et al). 1987;157:171-7
Amniocentesis; *see also* **Amniotic fluid**
Emotional responses of pregnant women to chorionic villi sampling or amniocentesis (Spencer and Cox). 1987;157:1155-60
Amnion
Progesterone synthesis by human amnion, chorion, and decidua at term (Mitchell et al). 1987;157:349-53
Amniotic fluid
Amniotic fluid discoloration caused by blood (Strickland and Hankins) (Letter); (Greve et al) (Reply). 1987;157:216-7
Amniotic fluid α-fetoprotein levels and pregnancy outcome (Brumfield et al). 1987;157:822-5
Amniotic fluid trypsin and premature rupture of membranes (McGregor et al) (Letter); (Kanayama) (Reply). 1987;157:1316-9
Antepartum fetal surveillance in the patient with decreased fetal movement (Ahn et al). 1987;157:860-4
Antepartum predictors of fetal distress in postterm pregnancy (Bochner et al). 1987;157:353-8
Arachidonate lipoxygenase metabolites in amniotic fluid of women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1454-60
Drug accumulation in lung fluid of the fetal lamb after maternal or fetal administration (Riggs et al). 1987;157:1286-91
Effects of alterations of zinc-to-phosphorus ratios and meconium content on Group B *Streptococcus* growth in human amniotic fluid in vitro (Hoskins et al). 1987;157:770-3
Infection and labor: the detection of endotoxin in amniotic fluid (Romero et al). 1987;157:815-9
Leukocyte esterase activity in human amniotic fluid for the rapid detection of chorioamnionitis (Hoskins et al). 1987;157:730-2
Prostaglandin concentrations in amniotic fluid of women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1461-7
Sonographic amniotic fluid measurement and fetal growth retardation: a reappraisal (Patterson et al). 1987;157:1406-10
Umbilical cord size and amniotic fluid volume in prolonged pregnancy (Silver et al). 1987;157:716-20
Androgens
Age-related changes in the female hormonal environment during reproductive life (Musey et al). 1987;157:312-7
Effect of chronically elevated androgen or estrogen on the glucose tolerance test and insulin response in female rhesus monkeys (Billiar et al). 1987;157:1297-302
Anemia
Intrapartum use of fetal scalp hematocrit in the diagnosis of profound fetal anemia caused by fetomaternal hemorrhage (Herman et al). 1987;157:1182-3
Red blood cell zinc protoporphyrin testing for iron-deficiency anemia in pregnancy (Schifman et al). 1987;157:304-7
Anencephaly
The binding and metabolism of low-density lipoprotein by skin fibroblasts of fetuses and newborns with anencephaly (Carr and Parker). 1987;157:1351-5
Circulating neurohypophyseal hormones in anencephalic infants (Oosterbaan and Swaab). 1987;157:117-9

Aneurysm
Mycotic aneurysms in pregnancy (Boike et al). 1987;157:340-1
Anomaly
Congenital heart block and cardiac anomalies in the absence of maternal connective tissue disease (Shenker et al). 1987;157:248-53
The detection of facial anomalies with ultrasound (Koontz) (Letter); (Pilu) (Reply). 1987;157:1316
Genetic implications of idiopathic hydramnios (Landy et al). 1987;157:114-7
Hypoglycemia: How little is too much for the embryo? (Sadler and Hunter). 1987;157:190-3
A hypothesis concerning the general basis of organogenetic congenital anomalies (Naftolin et al). 1987;157:1-4 (Clin. opinion)
Review of causes of perinatal mortality in a regional perinatal center, 1980 to 1984 (Ohlsson et al). 1987;157:443-5
Screening for genetic anomalies (Washburn) (Letter); (Macri) (Reply). 1987;157:212-3
Successful fetal therapy for cystic adenomatoid malformation associated with second-trimester hydrops (Clark et al). 1987;157:294-5
A very rare fetal malformation: the cutaneous widespread vascular hamartomatosis (Arienzo et al). 1987;157:1162-3
Anorexia nervosa
Anorexia nervosa, bulimia, and pregnancy (Stewart et al). 1987;157:1194-8
Antepartum hemorrhage
Fetal-induced trauma as a cause of antepartum hemorrhage (Eden). 1987;157:830-1
Antepartum testing
Antenatal diagnosis and management of monoamniotic twins (Rodis et al). 1987;157:1255-7
Antenatal diagnosis with ultrasonography (Shalev and Zuckerman) (Letter). 1987;157:1323
Antepartum fetal surveillance in the patient with decreased fetal movement (Ahn et al). 1987;157:860-4
Antepartum predictors of fetal distress in postterm pregnancy (Bochner et al). 1987;157:353-8
Antibiotics
Changing concepts in obstetric antibiotic prophylaxis (Galask). 1987;157:491-7
Cost-effective use of antibiotic prophylaxis for cesarean section (Ford et al). 1987;157:506-10
Prophylactic antibiotics for cesarean delivery: a simple cost-effective strategy for prevention of postoperative morbidity (Duff). 1987;157:794-8 (Clin. opinion)
Short course of antibiotics for post–cesarean section endometritis (Cabbad et al). 1987;157:908-9
Antibody
Diagnostic imaging of gynecologic tumors with the monoclonal antibody 791T/36 (Powell et al). 1987;157:28-34
Lymphocyte-reactive antibodies and recurrent early pregnancy failure (Biddle et al) (Letter). 1987;157:785-6
A pregnant woman with a high level of naturally occurring immunoglobulin M antibodies to *Toxoplasma gondii* (Konishi). 1987;157:832-3
The prevalence of autoantibodies in pregnant and nonpregnant women (Patton et al). 1987;157:1345-50
Recent developments in immunocontraception (Talwar and Gaur). 1987;157:1075-8
Varicella zoster antibody testing in the care of pregnant women exposed to varicella (McGregor et al). 1987;157:281-4
Anticoagulant
Second-trimester fetal monitoring and preterm delivery in pregnancies with systemic lupus erythematosus and/or circulating anticoagulant (Druzin et al). 1987;157:1503-10
Antiemetic
Drug accumulation in lung fluid of the fetal lamb after maternal or fetal administration (Riggs et al). 1987;157:1286-91
Antigen
An evaluation of squamous cell carcinoma antigen in patients with cervical squamous cell carcinoma (Senekjian et al). 1987;157:433-9
HLA antigen expression and induction by γ-interferon in cultured human trophoblasts (Feinman et al). 1987;157:1429-34
Human leukocyte antigen associated with endometrial carcinoma with a new classification of endometrial carcinoma based on its etiology (Kanuma and Igarashi). 1987;157:427-32
Recurrent spontaneous abortion and human leukocyte antigen DRw8 (Takamizawa et al) (Letter). 1987;157:514-5
Antiglobulin
Abnormalities in platelet antiglobulin tests in preeclamptic mothers and their neonates (Samuels et al). 1987;157:109-13
Antihistamine
Drug accumulation in lung fluid of the fetal lamb after maternal or fetal administration (Riggs et al). 1987;157:1286-91
Antiplasmin
Preeclampsia, delivery, and the hemostatic system (Saleh et al). 1987;157:331-6
Antiprogesterone
Effects of the antiprogesterone RU 486 in normal women. I. Single-dose administration in the midluteal phase (Shoupe et al). 1987;157:1415-20
Effects of the antiprogesterone RU 486 in normal women. II. Administration in the late follicular phase (Shoupe et al). 1987;157:1421-6
Effects of the antiprogesterone RU 486 on preterm birth in the rat (Garfield et al). 1987;157:1281-5
Endometrial and myometrial effects of progesterone antagonists in pregnant guinea pigs (Elger et al). 1987;157:1065-74
Temporal changes in uterine activity and prostaglandin response to RU 486 in rhesus macaques in late gestation (Haluska et al). 1987;157:1487-95
Antithrombin
Preeclampsia, delivery, and the hemostatic system (Saleh et al). 1987;157:331-6
Antithyroid drugs
Antithyroid drugs: to breast-feed or not to breast-feed (Cooper). 1987;157:234-5 (Clin. opinion)
Apgar score
The relationships among the fetal biophysical profile, umbilical cord pH, and Apgar scores (Vintzileos et al). 1987;157:627-31
Status of infants at birth and risk for adverse neonatal events and long-term sequelae: a study in low birth weight infants (Luthy et al). 1987;157:676-9
Umbilical cord blood pH and Apgar score as an index of neonatal health (Josten et al). 1987;157:843-8
Arachidonate lipoxygenase
Arachidonate lipoxygenase metabolites in amniotic fluid of

women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1454-60

Areoli
Breast galactography in the treatment of infected cysts (Tihansky and DiBlasio). 1987;157:1278-80

Arginine vasopressin
The effect of mild hypoxemia maintained for twenty-four hours on maternal and fetal glucose, lactate, cortisol, and arginine vasopressin in pregnant sheep at 122 to 139 days' gestation (Towell et al). 1987;157:1550-7

Aromatase
The effect of insulin on aromatase activity in isolated human endometrial glands and stroma (Randolph et al). 1987;157:1534-9

Arrhythmias; *see also* **Tachycardia**
Digoxin-like immunoreactive substance in fetuses with and without cardiac pathology (Weiner et al). 1987;157:368-71

Asphyxia
Indicators of perinatal asphyxia (Hollander et al). 1987;157:839-42
Review of causes of perinatal mortality in a regional perinatal center, 1980 to 1984 (Ohlsson et al). 1987;157:443-5

Aspiration biopsy; *see* **Biopsy**

Aspirin
Prevention of recurrent idiopathic fetal growth retardation by low-dose aspirin and dipyridamole (Wallenburg and Rotmans). 1987;157:1230-5

Association of Professors of Gynecology and Obstetrics
Presidential address of Association of Professors of Gynecology and Obstetrics (Weingold). 1987;157:799-802

Atherosis
Acute atherosis in preeclampsia: maternal determinants and fetal outcome in the presence of the lesion (Khong et al). 1987;157:360-3

Atrial natriuretic peptide
Plasma atrial natriuretic peptide response to volume expansion in the ovine fetus (Ross et al). 1987;157:1292-7

Auditory perception; *see also* **Acoustic stimulation**
Neonatal auditory acuity following in utero vibratory acoustic stimulation (Ohel et al). 1987;157:440-1
Fetal auditory brain stem response: effect of increasing stimulus rate during functional auditory development (Plessinger and Woods). 1987;157:1382-7

Autoantibody
The prevalence of autoantibodies in pregnant and nonpregnant women (Patton et al). 1987;157:1345-50

Autosome 13
A novel Y/13 familial translocation (Morris et al). 1987;157:857-8

B

Bacteria; *see also* **Infection**
Necrotizing fasciitis of the vulva (Roberts). 1987;157:568-71
The use and limitations of endocervical Gram stains and mucopurulent cervicitis as predictors for *Chlamydia trachomatis* in female adolescents (Moscicki et al). 1987;157:65-71

Bart's hemoglobin
Percutaneous ultrasound-guided fetal blood sampling in the management of nonimmune hydrops fetalis (Hsieh et al). 1987;157:44-9

Bereavement
Evaluation of a perinatal grief support team (Lake et al). 1987;157:1203-6

Biophysical profile
Fetal assessment based on fetal biophysical profile scoring: experience in 19,221 referred high-risk pregnancies. II. An analysis of false-negative fetal deaths (Manning et al). 1987;157:880-4
The use of fetal biophysical profile improves pregnancy outcome in premature rupture of the membranes (Vintzileos et al). 1987;157:236-40

Biopsy
Cervical endometriosis: facilitated diagnosis by fine needle aspiration cytologic testing (Veiga-Ferreira et al). 1987;157:849-56
Placental bed biopsy technique and vascular lesions (Labarrere) (Letter); (Robertson) (Reply). 1987;157:1320-2

Biparietal diameter
A sonographic screening method for Down syndrome (Lockwood et al). 1987;157:803-8

Birth; *see* **Delivery**

Birth weight
Growth hormone, somatomedin C, and nonsuppressible insulin-like activity levels compared in premature, small, average birth weight, and large infants (Samaan et al). 1987;157:1524-8
The relationship between cadmium, zinc, and birth weight in pregnant women who smoke (Kuhnert et al). 1987;157:1247-51
Ultrasonic prediction of birth weight in preterm fetuses: Which formula is best? (Pielet et al). 1987;157:1411-4

Black gravid women
Maternal serum α-fetoprotein screening. III. Pitfalls in evaluating black gravid women (Macri et al). 1987;157:820-2

Bladder polyp
Sonographic diagnosis of a bladder polyp (Jensen and Lynne). 1987;157:1168-9

Bleeding; *see also* **Hemorrhage**
First-trimester vaginal bleeding and the loss of chromosomally normal and abnormal conceptions (Strobino and Pantel-Silverman). 1987;157:1150-4

Blood
Amniotic fluid discoloration caused by blood (Strickland and Hankins) (Letter); (Greve et al) (Reply). 1987;157:216-7
Riboflavin concentration in maternal and cord blood in human pregnancy (Kirshenbaum et al). 1987;157:748-52

Blood flow
Changes in intracardiac Doppler blood flow velocities in fetuses with absent umbilical artery diastolic flow (Reed et al). 1987;157:774-9
Umbilical blood waveforms in fetal surveillance of twins (Saldana et al). 1987;157:712-5

Blood pressure; *see also* **Hypertension**
Blood pressure in the midtrimester and future eclampsia (Chesley and Sibai). 1987;157:1258-61
Vasopressin-induced bradycardia in fetal and adult sheep is not dependent on an increase in blood pressure (Harper and Rose). 1987;157:448-53

Blood sampling; *see also* **Cord blood**
Percutaneous ultrasound-guided fetal blood sampling in the management of nonimmune hydrops fetalis (Hsieh et al). 1987;157:44-9
Validity of intrapartum diagnosis of fetal thrombocytopenia (Christiaens and Helmerhorst). 1987;157:864-5

Blood volume
Measurement of human fetoplacental blood volume in erythroblastosis fetalis (Nicolaides et al). 1987;157:50-3
Plasma atrial natriuretic peptide response to volume expansion in the ovine fetus (Ross et al). 1987;157:1292-7

Books received
Books received. 1987;157:227, 519, 787, 1017, 1561
Bowel obstruction
Mechanical intestinal obstruction in patients with gynecologic disease: a review of 368 patients (Krebs and Goplerud). 1987;157:577-83
Bradycardia
Vasopressin-induced bradycardia in fetal and adult sheep is not dependent on an increase in blood pressure (Harper and Rose). 1987;157:448-53
Brain death
The pregnant brain dead and the fetus: Must we always try to wrest life from death? (Loewy). 1987;157:1097-101 (Clin. opinion)
Breast
Breast galactography in the treatment of infected cysts (Tihansky and DiBlasio). 1987;157:1278-80
Breast stimulation test and oxytocin challenge test in fetal surveillance: a prospective randomized study (Lipitz et al). 1987;157:1178-81
Cigarette smoking and the risk of female reproductive cancer (Stockwell and Lyman). 1987;157:35-40
Breast-feeding
Antithyroid drugs: to breast-feed or not to breast-feed (Cooper). 1987;157:234-5 (Clin. opinion)
Mexiletine use in pregnancy and lactation (Lownes and Ives). 1987;157:446-7
Bromide
Cord serum bromide concentration: variation and lack of association with pregnancy outcome (Miller et al). 1987;157:826-30
Bruising
Erb's palsy and fetal bruising after external cephalic version: case report (Petrikovsky et al). 1987;157:258
Bulimia
Anorexia nervosa, bulimia, and pregnancy (Stewart et al). 1987;157:1194-8

C

CA-125
Evaluation of serum CA 125 levels in the monitoring of ovarian cancer (Vergote et al). 1987;157:88-92
Serum CA-125 in the evaluation of benign adnexal cysts (Pittaway et al). 1987;157:1426-8
Cadmium
The effect of smoking on placental and fetal zinc status (Kuhnert et al). 1987;157:1241-6
The relationship between cadmium, zinc, and birth weight in pregnant women who smoke (Kuhnert et al). 1987;157:1247-51
Caffeine
Caffeine-cigarette interaction on fetal growth (Beaulac-Baillargeon and Desrosiers). 1987;157:1236-40
The effects of long- and short-term maternal caffeine ingestion on human fetal breathing and body movements in term gestations (McGowan et al). 1987;157:726-9
Calcium
Effects of calcium entry blocker (nicardipine) tocolysis in rhesus macaques: fetal plasma concentrations and cardiorespiratory changes (Ducsay et al). 1987;157:1482-6
A new look at uterine muscle contraction (Carsten and Miller). 1987;157:1303-15 (Curr. dev.)
Nifedipine: effects on fetal and maternal hemodynamics in pregnant sheep (Harake et al). 1987;157:1003-8
Cancer; *see* **Carcinoma**
Capillary hydrostatic pressure
Calculated capillary hydrostatic pressure in normal pregnancy and preeclampsia (Øian and Maltau). 1987;157:102-6
Carbacyclin
Cyclooxygenase inhibition reduces placental transfer: reversal by carbacyclin (Kuhn and Stuart). 1987;157:194-8
Carbohydrates; *see also* **Cerebral glucose**
The "breakfast tolerance test": screening for gestational diabetes with a standardized mixed nutrient meal (Coustan et al). 1987;157:1113-7
Carbon dioxide laser
Carbon dioxide laser laparoscopy performed with a flexible fiber in humans (Baggish et al). 1987;157:1129-33
Carcinoma; *see also* **Malignancy; Neoplasia; Tumor**
Adenosquamous carcinoma of the fallopian tube: a clinicopathologic case report with verification of the diagnosis by immunohistochemical and ultrastructural studies (Moore et al). 1987;157:903-5
The anatomic distribution of cervical adenocarcinoma in situ: implications for treatment (Bertrand et al). 1987;157:21-5
Another look at the second-assessment procedure for ovarian epithelial carcinoma (Gallup et al). 1987;157:590-6
Cigarette smoking and the risk of female reproductive cancer (Stockwell and Lyman). 1987;157:35-40
Decreasing incidence of invasive cervical cancer in young women (Chu and White). 1987;157:1105-7
Endometrial metaplasia associated with endometrial adenocarcinoma (Andersen et al). 1987;157:597-604
Evaluation of serum CA 125 levels in the monitoring of ovarian cancer (Vergote et al). 1987;157:88-92
An evaluation of squamous cell carcinoma antigen in patients with cervical squamous cell carcinoma (Senekjian et al). 1987;157:433-9
Histologic composition of endometrial carcinomas analyzed for steroid receptor content (Soper et al). 1987;157:26-7
Human leukocyte antigen associated with endometrial carcinoma with a new classification of endometrial carcinoma based on its etiology (Kanuma and Igarashi). 1987;157:427-32
Multiple primary gynecologic neoplasms (Rose et al). 1987;157:261-7
Racial differences in survival of women with endometrial cancer (Bain et al). 1987;157:914-23
Cardiac anomaly; *see also* **Anomaly**
Congenital heart block and cardiac anomalies in the absence of maternal connective tissue disease (Shenker et al). 1987;157:248-53
Catecholamines
Acute effects of exercise on plasma catecholamines in sedentary and athletic women with normal and abnormal menses (Chin et al). 1987;157:938-44
Cell volume
γ-Glutamyl transferase and mean cell volume reveal maternal alcohol abuse and fetal alcohol effects (Ylikorkala et al). 1987;157:344-8
Cephalic version
Erb's palsy and fetal bruising after external cephalic version: case report (Petrikovsky et al). 1987;157:258
Cerclage
Management of the diethylstilbestrol-exposed pregnant patient: a prospective study (Ludmir et al). 1987;157:665-9
Cerebellum
Fetal cerebellar growth unaffected by intrauterine growth

retardation: a new parameter for prenatal diagnosis (Reece et al). 1987;157:632-8

Cerebral glucose
Effects of cochlear ablation on local cerebral glucose utilization in fetal sheep (Abrams et al). 1987;157:1438-42
Local cerebral glucose utilization in fetal sheep exposed to noise (Abrams et al). 1987;157:456-60

Cerebral metabolism; *see also* **Cerebral glucose**
Cerebral oxidative metabolism in fetal sheep with multiple-dose ethanol infusion (Richardson et al). 1987;157:1496-502

Cerebral palsy
Status of infants at birth and risk for adverse neonatal events and long-term sequelae: a study in low birth weight infants (Luthy et al). 1987;157:676-9

Cerebrospinal fluid
Cerebrospinal fluid levels of magnesium in patients with preeclampsia after treatment with intravenous magnesium sulfate: a preliminary report (Thurnau et al). 1987;157:1435-8

Cervical intraepithelial neoplasia
Colposcopic correlates of cervical papillomavirus infection (Follen et al). 1987;157:809-14
Evaluation of the atypical Pap smear (Jones et al). 1987;157:544-9
Laser excisional conization and laser vaporization for cervical intraepithelial neoplasia (Anderson) (Letter); (Baggish) (Reply). 1987;157:1322-3
The results of cryosurgical treatment of cervical intraepithelial neoplasia at one, five, and ten years (Benedet et al). 1987;157:268-73

Cervicitis
Detection of *Chlamydia trachomatis* cervical infection: a comparison of Papanicolaou and immunofluorescent staining with cell culture (Quinn et al). 1987;157:394-9
The use and limitations of endocervical Gram stains and mucopurulent cervicitis as predictors for *Chlamydia trachomatis* in female adolescents (Moscicki et al). 1987;157:65-71

Cervix; *see also* **Cervical intraepithelial neoplasia; Cervicitis**
The anatomic distribution of cervical adenocarcinoma in situ: implications for treatment (Bertrand et al). 1987;157:21-5
Cervical endometriosis: facilitated diagnosis by fine needle aspiration cytologic testing (Veiga-Ferreira et al). 1987;157:849-56
Correlation between chlamydia infection and clinical evaluation, vaginal wet smear, and cervical swab test in female adolescents (Thejls et al). 1987;157:974-6
Decreased elastic fibers and desmosine content in incompetent cervix (Leppert et al). 1987;157:1134-9
Decreasing incidence of invasive cervical cancer in young women (Chu and White). 1987;157:1105-7
An evaluation of squamous cell carcinoma antigen in patients with cervical squamous cell carcinoma (Senekjian et al). 1987;157:433-9
Langerhans' cells in the cervix (Hawthorn and MacLean) (Letter); (McArdle) (Reply). 1987;157:213-5
Management of the diethylstilbestrol-exposed pregnant patient: a prospective study (Ludmir et al). 1987;157:665-9
Sonographic evaluation of the cervix during ovulation induction (Hill et al). 1987;157:1170-4

Cesarean section
Careful surgical technique can reduce infectious morbidity after cesarean section (Lyon and Richardson). 1987;157:557-62
Cost-effective use of antibiotic prophylaxis for cesarean section (Ford et al). 1987;157:506-10
Neonatal seizures after cesarean delivery: higher risk with labor (Spellacy et al). 1987;157:377-9
The pregnant brain dead and the fetus: Must we always try to wrest life from death? (Loewy). 1987;157:1097-101 (Clin. opinion)
Previous cesarean delivery and trial of labor (Fribourg) (Letter); (Finley) (Reply). 1987;157:1014-5
Primary cesarean section and subsequent fertility (LaSala and Berkeley). 1987;157:379-83
Prophylactic antibiotics for cesarean delivery: a simple cost-effective strategy for prevention of postoperative morbidity (Duff). 1987;157:794-8 (Clin. opinion)
A prospective randomized study of the aggressive management of early labor (Cohen et al). 1987;157:1174-7
The relationships among the fetal biophysical profile, umbilical cord pH, and Apgar scores (Vintzileos et al). 1987;157:627-31
Risk of vaginal delivery after a prior cesarean section (Catanzarite) (Letter). 1987;157:213
Short course of antibiotics for post–cesarean section endometritis (Cabbad et al). 1987;157:908-9
Single-dose versus multiple-dose piperacillin prophylaxis in primary cesarean operation (Gall and Hill). 1987;157:502-6
Vaginal birth after cesarean (Phelan et al). 1987;157:1510-5

Chemicals
Disruption of embryonic and fetal development due to preimplantation chemical insults: a critical review (Iannaccone et al). 1987;157:476-84 (Curr. dev.)

Chemotaxis
Cost-effective use of antibiotic prophylaxis for cesarean section (Ford et al). 1987;157:506-10
Host defense during pregnancy: neutrophil chemotaxis and adherence (Krause et al). 1987;157:274-80

Chlamydia trachomatis
Correlation between chlamydia infection and clinical evaluation, vaginal wet smear, and cervical swab test in female adolescents (Thejls et al). 1987;157:974-6
Detection of *Chlamydia trachomatis* cervical infection: a comparison of Papanicolaou and immunofluorescent staining with cell culture (Quinn et al). 1987;157:394-9
The use and limitations of endocervical Gram stains and mucopurulent cervicitis as predictors for *Chlamydia trachomatis* in female adolescents (Moscicki et al). 1987;157:65-71

Chloroaminobenzoic acid
2-Chloroprocaine for local perineal infiltration (Philipson et al). 1987;157:1275-8

2-Chloroprocaine
2-Chloroprocaine for local perineal infiltration (Philipson et al). 1987;157:1275-8

Cholesteryl palmitate
Cholesteryl palmitate as a predictor of fetal lung maturity (Ludmir et al). 1987;157:84-8

Chorioamnionitis
Leukocyte esterase activity in human amniotic fluid for the rapid detection of chorioamnionitis (Hoskins et al). 1987;157:730-2

Chorion
Progesterone synthesis by human amnion, chorion, and decidua at term (Mitchell et al). 1987;157:349-53

Chorionic gonadotropin; *see* **Gonadotropins**
Chorionic villus
Chorionic villus sampling is associated with normal fetal growth (Williams et al). 1987;157:708-12
Echocardiographic and anatomic studies of the maternotrophoblastic border during the first trimester of pregnancy (Hustin and Schaaps). 1987;157:162-8
Emotional responses of pregnant women to chorionic villi sampling or amniocentesis (Spencer and Cox). 1987;157:1155-60
The immediate effects of chorionic villus sampling on fetal movements (Boogert et al). 1987;157:137-9
Transabdominal chorionic villus sampling: a freehand ultrasound-guided technique (Brambati et al). 1987;157:134-7
Cigarette smoking; *see* **Smoking**
Clinical opinion
Clinical opinion. 1987;157:1-9, 229-35, 789-98, 1093-101
Clomiphene
Absence of clomiphene and/or active metabolites in blood of clomiphene citrate–treated patients during organogenesis: determination by radioreceptor assay (Geier et al) (Letter). 1987;157:1009
Coagulation; *see also* **Blood; Hemorrhage**
Coagulation effects of oral contraception (Bonnar). 1987;157:1042-8
Cocaine
Cocaine use during pregnancy: adverse perinatal outcome (MacGregor et al). 1987;157:686-90
Cochlear ablation
Effects of cochlear ablation on local cerebral glucose utilization in fetal sheep (Abrams et al). 1987;157:1438-42
Colloid osmotic pressure
Mechanisms for reduced colloid osmotic pressure in preeclampsia (Bhatia et al). 1987;157:106-8
Colposcopy
Colposcopic correlates of cervical papillomavirus infection (Follen et al). 1987;157:809-14
Colposcopic evaluation of abnormal Papanicolaou smears in pregnancy (Benedet et al). 1987;157:932-7
Evaluation of the atypical Pap smear (Jones et al). 1987;157:544-9
Congenital anomaly; *see* **Anomaly**; *specific anomaly*
Congenital heart disease
Congenital heart block and cardiac anomalies in the absence of maternal connective tissue disease (Shenker et al). 1987;157:248-53
Fetal echocardiographic screening for congenital heart disease: the importance of the four-chamber view (Copel et al). 1987;157:648-55
Conization
Laser excisional conization and laser vaporization for cervical intraepithelial neoplasia (Anderson) (Letter); (Baggish) (Reply). 1987;157:1322-3
Connective tissue disease
Congenital heart block and cardiac anomalies in the absence of maternal connective tissue disease (Shenker et al). 1987;157:248-53
Consultants
Consultants for the American Journal of Obstetrics and Gynecology. 1987;157:1325-32
Contraception
Coagulation effects of oral contraception (Bonnar). 1987;157:1042-8
Contraception: an overview (Hammerstein). 1987;157:1020-3
Contraceptive use, pelvic inflammatory disease, and fertility problems among American women: 1982 (Aral et al). 1987;157:59-64
Experiences with gossypol as a male pill (Liu et al). 1987;157:1079-81
Hormonal contraception: benefits versus risks (Goldzieher). 1987;157:1023-8
International symposium on contraception. Part 1: oral contraception. 1987;157:1019-63
International symposium on contraception. Part I: oral contraception: introduction (Speroff). 1987;157:1019
International symposium on contraception. Part 2: alternative methods of contraception. 1987;157:1064-92
International symposium on contraception. Part 2: alternative methods of contraception: introduction (Diczfalusy). 1987;157:1064
Metabolic effects of oral contraceptives (Gaspard). 1987;157:1029-41
Natural family planning (Brown et al). 1987;157:1082-9
A new delivery system for contraceptive steroids (Segal). 1987;157:1090-2
New progestogens in oral contraceptives (Runnebaum and Rabe). 1987;157:1059-63
Phasic approach to oral contraceptives (Hale). 1987;157:1052-8
Progestogen potency in oral contraceptive pills (Gillmer). 1987;157:1048-52
Updated pregnancy rates for the Today contraceptive sponge (Edelman and North). 1987;157:1164-5
Venous thrombosis in patients with cardiac pacemakers and oral contraceptive use (Rao) (Letter). 1987;157:516-7
Contraction
A new look at uterine muscle contraction (Carsten and Miller). 1987;157:1303-15 (Curr. dev.)
A prospective evaluation of nipple stimulation techniques for contraction stress testing (Keegan et al). 1987;157:121-5
Copper
Serum copper level in gynecologic malignancies (Margalioth et al). 1987;157:93-6
Cord; *see* **Umbilical cord**
Cord blood
Cord sampling for the evaluation of oxygenation and acid-base balance in human growth-retarded fetuses (Pardi et al). 1987;157:1221-8
Cord serum bromide concentration: variation and lack of association with pregnancy outcome (Miller et al). 1987;157:826-30
Enhancement of maternal and neonatal natural killer cell activity with interleukin-2 (Baker et al). 1987;157:780-1
The relationships among the fetal biophysical profile, umbilical cord pH, and Apgar scores (Vintzileos et al). 1987;157:627-31
Riboflavin concentration in maternal and cord blood in human pregnancy (Kirshenbaum et al). 1987;157:748-52
Status of infants at birth and risk for adverse neonatal events and long-term sequelae: a study in low birth weight infants (Luthy et al). 1987;157:676-9
Umbilical cord blood pH and Apgar score as an index of neonatal health (Josten et al). 1987;157:843-8
Cordotomy
The effect of severing the spinal cord of fetal lambs on length of gestation (Nowak et al). 1987;157:464-7
Coronary heart disease
Menstrual and reproductive factors and the risk of myo-

cardial infarction in women under 55 years of age (La Vecchia et al). 1987;157:1108-12

Corrections

Echocardiographic and anatomic studies of the maternotrophoblastic border during the first trimester of pregnancy (Hustin and Schaaps) (1987;157:162-8). 1987; 157:1291

Effects of maternal anemia on cardiac output, systemic oxygen consumption, and regional blood flow in pregnant sheep (Edelstone et al) (1987;156:740-8). 1987;157:1291

Inhibition of prolactin secretion by antiserum to the α-and β-subunits of gonadotropin (Blackwell and Garrison) (1987;156:863-8). 1987;157:1520

Predictive value of early pregnancy glycohemoglobin in the insulin-treated diabetic patient (Key et al) (1987;156:1096-100). 1987;157:1460

Proportional weight gain and complications of pregnancy, labor, and delivery in healthy women of normal prepregnant stature (Shepard et al) (1986;155:947-54). 1987;157:217

The role of platelet-activating factor in human fetal lung maturation (Hoffman et al) (1986;155:70-5). 1987; 157:179

Correspondence

Letters. 1987;157:212-7, 513-8, 782-6, 1009-16, 1316-23

Corticotropin-releasing hormone

Pituitary responses to synthetic corticotropin-releasing hormone: absence of modulatory effects by estrogen and progestin (Liu et al). 1987;157:1387-91

Cortisol

The effect of mild hypoxemia maintained for twenty-four hours on maternal and fetal glucose, lactate, cortisol, and arginine vasopressin in pregnant sheep at 122 to 139 days' gestation (Towell et al). 1987;157:1550-7

Creatinine phosphokinase

Indicators of perinatal asphyxia (Hollander et al). 1987;157:839-42

Cryosurgery

The results of cryosurgical treatment of cervical intraepithelial neoplasia at one, five, and ten years (Benedet et al). 1987;157:268-73

Curettage

The value of curettage in the diagnosis of ectopic pregnancy (Ollendorff et al). 1987;157:71-2

Current development

Current development. 1987;157:180-4, 476-84, 1303-15

Cyclic adenosine monophosphate

Changes in cyclic adenosine monophosphate–phosphodiesterase activity in nonpregnant and pregnant human myometrium (Kofinas et al). 1987;157:733-8

A new look at uterine muscle contraction (Carsten and Miller). 1987;157:1303-15 (Curr. dev.)

Cyclooxygenase

Cyclooxygenase inhibition reduces placental transfer: reversal by carbacyclin (Kuhn and Stuart). 1987;157:194-8

Cystic adenomatoid malformation

Successful fetal therapy for cystic adenomatoid malformation associated with second-trimester hydrops (Clark et al). 1987;157:294-5

Cysts

Breast galactography in the treatment of infected cysts (Tihansky and DiBlasio). 1987;157:1278-80

Serum CA-125 in the evaluation of benign adnexal cysts (Pittaway et al). 1987;157:1426-8

Theca-lutein ovarian cysts associated with homozygous α-thalassemia (Miller et al). 1987;157:912-4

Cytogenetics

Hydatidiform mole: cytogenetically unusual cases and their implications for the present classification (Vejerslev et al). 1987;157:180-4 (Curr. dev.)

Fetal death: diagnosis and management (Pitkin). 1987;157:583-9

Decidua

Progesterone synthesis by human amnion, chorion, and decidua at term (Mitchell et al). 1987;157:349-53

Steroid synthetic and prostaglandin metabolizing activity is present in different cell populations from human fetal membranes and decidua (Challis and Vaughan). 1987;157:1474-81

Delivery; *see also* **Preterm labor and delivery**

Preeclampsia, delivery, and the hemostatic system (Saleh et al). 1987;157:331-6

Risk of vaginal delivery after a prior cesarean section (Catanzarite) (Letter). 1987;157:213

Second-trimester fetal monitoring and preterm delivery in pregnancies with systemic lupus erythematosus and/or circulating anticoagulant (Druzin et al). 1987;157:1503-10

Status of infants at birth and risk for adverse neonatal events and long-term sequelae: a study in low birth weight infants (Luthy et al). 1987;157:676-9

Deoxyribonucleic acid

Partial hydatidiform moles: deoxyribonucleic acid content and course (David et al). 1987;157:969-73

Desmosine

Decreased elastic fibers and desmosine content in incompetent cervix (Leppert et al). 1987;157:1134-9

Diabetes mellitus

The "breakfast tolerance test": screening for gestational diabetes with a standardized mixed nutrient meal (Coustan et al). 1987;157:1113-7

Early third-trimester ultrasound screening in gestational diabetes to determine the risk of macrosomia and labor dystocia at term (Bochner et al). 1987;157:703-8

Gestational diabetes: insulin requirements in pregnancy (Langer et al). 1987;157:669-75

Gestational diabetes: maternal response to diet and insulin therapy as reflected by glycosylated hemoglobin concentration (Grandis et al). 1987;157:1118-21

A hypothesis concerning the general basis of organogenetic congenital anomalies (Naftolin et al). 1987;157:1-4 (Clin. opinion)

Necrotizing fasciitis of the vulva (Roberts). 1987;157:568-71

Postprandial walking exercise in pregnant insulin-depen-

dent (type 1) diabetic women: reduction of plasma lipid levels but absence of a significant effect on glycemic control (Hollingsworth and Moore). 1987;157:1359-63
The reliability and clinical use of a rapid phosphatidylglycerol assay in normal and diabetic pregnancies (Saad et al). 1987;157:1516-20
Restriction fragment length polymorphisms of the insulin gene hypervariable region in gestational onset diabetes mellitus (Ober et al). 1987;157:1364-8
The significance of one abnormal glucose tolerance test value on adverse outcome in pregnancy (Langer et al). 1987;157:758-63
Verified self-monitored blood glucose data versus glycosylated hemoglobin and glycosylated serum protein as a means of predicting short-and long-term metabolic control in gestational diabetes (Brustman et al). 1987;157:699-703

Diagnostic imaging
Diagnostic imaging of gynecologic tumors with the monoclonal antibody 791T/36 (Powell et al). 1987;157:28-34

Diet
Gestational diabetes: maternal response to diet and insulin therapy as reflected by glycosylated hemoglobin concentration (Grandis et al). 1987;157:1118-21

Diethylstilbestrol
Management of the diethylstilbestrol-exposed pregnant patient: a prospective study (Ludmir et al). 1987;157:665-9

Digoxin
Digoxin-like immunoreactive substance in fetuses with and without cardiac pathology (Weiner et al). 1987;157:368-71
Digoxin-like immunoreactive substance in pregnancy (Gonzalez et al). 1987;157:660-4
Insufficient transplacental digoxin transfer in severe hydrops fetalis (Younis and Granat). 1987;157:1268-9

Diphenhydramine
Drug accumulation in lung fluid of the fetal lamb after maternal or fetal administration (Riggs et al). 1987;157:1286-91

Dipyridamole
Prevention of recurrent idiopathic fetal growth retardation by low-dose aspirin and dipyridamole (Wallenburg and Rotmans). 1987;157:1230-5

Doppler study
Changes in intracardiac Doppler blood flow velocities in fetuses with absent umbilical artery diastolic flow (Reed et al). 1987;157:774-9
A classification of hypertension in pregnancy based on Doppler velocimetry (Ducey et al). 1987;157:680-5
Renal arterial blood flow velocity waveforms in pregnant women (Hata et al). 1987;157:1269-71
Umbilical artery flow velocity waveforms and the placental vascular bed (McCowan et al). 1987;157:900-2
Uterine artery Doppler velocimetry: the significance of divergent systolic/diastolic ratios (Shulman et al). 1987;157:1539-42
Uterine and umbilical artery velocimetry during normal labor (Fleischer et al). 1987;157:40-3

Down syndrome
Soft tissue nuchal fold in the second-trimester fetus: standards for normal measurements compared with those in Down syndrome (Benacerraf and Frigoletto). 1987;157:1146-9
A sonographic screening method for Down syndrome (Lockwood et al). 1987;157:803-8

Drug abuse
Cocaine use during pregnancy: adverse perinatal outcome (MacGregor et al). 1987;157:686-90
γ-Glutamyl transferase and mean cell volume reveal maternal alcohol abuse and fetal alcohol effects (Ylikorkala et al). 1987;157:344-8
Mycotic aneurysms in pregnancy (Boike et al). 1987;157:340-1

Drugs
Disruption of embryonic and fetal development due to preimplantation chemical insults: a critical review (Iannaccone et al). 1987;157:476-84 (Curr. dev.)
Drug accumulation in lung fluid of the fetal lamb after maternal or fetal administration (Riggs et al). 1987;157:1286-91
Drug prescribing for thromboembolic disease during pregnancy (Greenspoon and Montoro) (Letter). 1987;157:784-5
Prescription drug use before and during pregnancy in a Medicaid population (Piper et al). 1987;157:148-56

DRw8 antigen
Recurrent spontaneous abortion and human leukocyte antigen DRw8 (Takamizawa et al) (Letter). 1987;157:514-5

Dysmenorrhea
Simultaneous objective and subjective evaluation of meclofenamate sodium in the treatment of primary dysmenorrhea (Smith and Powell). 1987;157:611-8

Dystocia
Early third-trimester ultrasound screening in gestational diabetes to determine the risk of macrosomia and labor dystocia at term (Bochner et al). 1987;157:703-8
A prospective randomized study of the aggressive management of early labor (Cohen et al). 1987;157:1174-7

E

Eating disorders
Anorexia nervosa, bulimia, and pregnancy (Stewart et al). 1987;157:1194-8

Echocardiography
Echocardiographic and anatomic studies of the maternotrophoblastic border during the first trimester of pregnancy (Hustin and Schaaps). 1987;157:162-8
Fetal echocardiographic screening for congenital heart disease: the importance of the four-chamber view (Copel et al). 1987;157:648-55

Eclampsia; *see also* **Preeclampsia**
Blood pressure in the midtrimester and future eclampsia (Chesley and Sibai). 1987;157:1258-61

Ectopic pregnancy
Abdominal pregnancy: magnetic resonance identification with ultrasonographic follow-up of placental involution (Spanta et al). 1987;157:887-9
Conservative surgical management of isthmic ectopic pregnancies (Smith et al). 1987;157:604-10
First-trimester serum levels of the β-subunit of human chorionic gonadotropin in a tubal molar pregnancy (Chase et al). 1987;157:910
Hysterosalpingographic evaluation of tubal patency after ectopic pregnancy (Mitchell et al). 1987;157:618-22
The value of curettage in the diagnosis of ectopic pregnancy (Ollendorff et al). 1987;157:71-2

Effusion
Pleural effusions and pulmonary hypoplasia (Castillo et al). 1987;157:1252-5

Elastic fiber
Decreased elastic fibers and desmosine content in incompetent cervix (Leppert et al). 1987;157:1134-9
Electrolytes
The nonpredictive value of fetal urinary electrolytes: preliminary report of outcomes and correlation with pathologic diagnosis (Wilkins et al). 1987;157:694-8
Electromyography
Characteristics of the electromyogram recorded from the mesometrium of the pregnant ewe from 106 days' gestation to delivery: similarities with and differences from the electromyogram obtained from the myometrium (Figueroa et al). 1987;157:991-8
Electron microscopy
Adenosquamous carcinoma of the fallopian tube: a clinicopathologic case report with verification of the diagnosis by immunohistochemical and ultrastructural studies (Moore et al). 1987;157:903-5
Electronic fetal monitoring; *see* **Fetal monitoring**
Electrophoresis
Seminal plasma proteins of fertile and infertile men analyzed by two-dimensional electrophoresis (Ayyagari et al). 1987;157:1528-33
Embolization
Umbilical artery flow velocity waveforms and placental resistance: the effects of embolization of the umbilical circulation (Trudinger et al). 1987;157:1443-8
Embryo
Disruption of embryonic and fetal development due to preimplantation chemical insults: a critical review (Iannaccone et al). 1987;157:476-84 (Curr. dev.)
Human embryo viability related to freezing and thawing procedures (Testart et al). 1987;157:168-71
Hypoglycemia: How little is too much for the embryo? (Sadler and Hunter). 1987;157:190-3
Emotions; *see also* **Psychological adjustment**
Emotional responses of pregnant women to chorionic villi sampling or amniocentesis (Spencer and Cox). 1987;157:1155-60
Endometrial carcinoma
Cigarette smoking and the risk of female reproductive cancer (Stockwell and Lyman). 1987;157:35-40
Endometrial adenocarcinoma estrogen receptor content: association of clinicopathologic features with immunohistochemical analysis compared with standard biochemical methods (Mutch et al). 1987;157:924-31
Endometrial metaplasia associated with endometrial adenocarcinoma (Andersen et al). 1987;157:597-604
Histologic composition of endometrial carcinomas analyzed for steroid receptor content (Soper et al). 1987;157:26-7
Human leukocyte antigen associated with endometrial carcinoma with a new classification of endometrial carcinoma based on its etiology (Kanuma and Igarashi). 1987;157:427-32
Racial differences in survival of women with endometrial cancer (Bain et al). 1987;157:914-23
Endometriosis
Cervical endometriosis: facilitated diagnosis by fine needle aspiration cytologic testing (Veiga-Ferreira et al). 1987;157:849-56
Effect of pregnancy on surgically induced endometriosis in cynomolgus monkeys (Schenken et al). 1987;157:1392-6
Local peritoneal factors: their role in infertility associated with endometriosis (Awadalla et al). 1987;157:1207-14
The morphologic effect of short-term medical therapy of endometriosis (Brosens et al). 1987;157:1215-21
Endometritis
Prophylactic antibiotics for cesarean delivery: a simple cost-effective strategy for prevention of postoperative morbidity (Duff). 1987;157:794-8 (Clin. opinion)
Short course of antibiotics for post–cesarean section endometritis (Cabbad et al). 1987;157:908-9
Endometrium
Characteristics of the electromyogram recorded from the mesometrium of the pregnant ewe from 106 days' gestation to delivery: similarities with and differences from the electromyogram obtained from the myometrium (Figueroa et al). 1987;157:991-8
The effect of insulin on aromatase activity in isolated human endometrial glands and stroma (Randolph et al). 1987;157:1534-9
Endometrial and myometrial effects of progesterone antagonists in pregnant guinea pigs (Elger et al). 1987;157:1065-74
Suppression of lymphocyte reactivity in vitro by supernatants of explants of human endometrium (Wang et al). 1987;157:956-63
β-Endorphin
Proopiomelanocortin-related peptides and methionine enkephalin in human follicular fluid: changes during the menstrual cycle (Petraglia et al). 1987;157:142-6
Endotoxin
Infection and labor: the detection of endotoxin in amniotic fluid (Romero et al). 1987;157:815-9
Energy metabolism
Placental glycolysis and energy metabolism in preeclampsia (Bloxam et al). 1987;157:97-101
Enzyme immunoassay
Natural family planning (Brown et al). 1987;157:1082-9
Enzymes
Increased tubular enzyme excretion in preeclampsia (Goren et al). 1987;157:906-8
Epithelial carcinoma
Another look at the second-assessment procedure for ovarian epithelial carcinoma (Gallup et al). 1987;157:590-6
Erb's palsy
Erb's palsy and fetal bruising after external cephalic version: case report (Petrikovsky et al). 1987;157:258
Errata; *see* **Corrections**
Erythroblastosis fetalis
Measurement of human fetoplacental blood volume in erythroblastosis fetalis (Nicolaides et al). 1987;157:50-3
Estradiol
Modulating actions of estradiol on gonadotropin-releasing hormone–stimulated prolactin secretion in postmenopausal individuals (Christiansen et al). 1987;157:320-5
Estriol
Human chorionic gonadotropin, estriol, and testosterone changes in two pregnancies with hyperreactio luteinalis (Muechler et al). 1987;157:1126-8
Estrogens
Age-related changes in the female hormonal environment during reproductive life (Musey et al). 1987;157:312-7
Coagulation effects of oral contraception (Bonnar). 1987;157:1042-8
Continuous estrogen/progestin therapy in menopause (Prough et al). 1987;157:1449-53
Effect of chronically elevated androgen or estrogen on the glucose tolerance test and insulin response in female rhesus monkeys (Billiar et al). 1987;157:1297-302
Endometrial adenocarcinoma estrogen receptor content: association of clinicopathologic features with immunohis-

tochemical analysis compared with standard biochemical methods (Mutch et al). 1987;157:924-31
Estrogen, progesterone, prolactin, prostaglandin E_2, prostaglandin $F_{2\alpha}$, 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$, and 6-keto-prostaglandin $F_{1\alpha}$ gradients across the uterus in women in labor and not in labor (Davidson et al). 1987;157:54-8
Evidence that estrogen may be a key factor in hyperprolactinemic anovulation: a case report (Sakamoto et al). 1987;157:318-9
Histologic composition of endometrial carcinomas analyzed for steroid receptor content (Soper et al). 1987;157:26-7
Menstrual and reproductive factors and the risk of myocardial infarction in women under 55 years of age (La Vecchia et al). 1987;157:1108-12
Natural family planning (Brown et al). 1987;157:1082-9
Pituitary responses to synthetic corticotropin-releasing hormone: absence of modulatory effects by estrogen and progestin (Liu et al). 1987;157:1387-91

Ethanol; *see also* **Alcohol**
Cerebral oxidative metabolism in fetal sheep with multiple-dose ethanol infusion (Richardson et al). 1987;157:1496-502
Disposition of acute, multiple-dose ethanol in the near-term pregnant ewe (Brien et al). 1987;157:204-11

Ethics
When does a statistical fact become an ethical imperative? (Silver and Minogue). 1987;157:229-33 (Clin. opinion)

Exercise
Acute effects of exercise on plasma catecholamines in sedentary and athletic women with normal and abnormal menses (Chin et al). 1987;157:938-44
Effects of aerobic and strength conditioning on pregnancy outcomes (Hall and Kaufmann). 1987;157:1199-203

F

Facial anomaly
The detection of facial anomalies with ultrasound (Koontz) (Letter); (Pilu) (Reply). 1987;157:1316

Factor XI deficiency
Factor XI deficiency presenting as hemarthrosis during pregnancy (Musclow et al). 1987;157:178-9

Fallopian tube
Adenosquamous carcinoma of the fallopian tube: a clinicopathologic case report with verification of the diagnosis by immunohistochemical and ultrastructural studies (Moore et al). 1987;157:903-5

False results
Definitions of sensitivity, specificity, false negative results, and false positive results (Kolins) (Letter). 1987;157:517-8
Fetal assessment based on fetal biophysical profile scoring: experience in 19,221 referred high-risk pregnancies. II. An analysis of false-negative fetal deaths (Manning et al). 1987;157:880-4

Femininity
Femininity—a problem(?) (Eichner) (Letter). 1987;157:517

Femur
Fetal weight estimation formulas with head, abdominal, femur, and thigh circumference measurements (Vintzileos et al). 1987;157:410-4

Fertilization; *see also* **Infertility**
Sonographic evaluation of the cervix during ovulation induction (Hill et al). 1987;157:1170-4
Transurethral ultrasound-guided oocyte retrieval for in vitro fertilization (Padilla et al). 1987;157:622-6

Fetal alcohol syndrome
γ-Glutamyl transferase and mean cell volume reveal maternal alcohol abuse and fetal alcohol effects (Ylikorkala et al). 1987;157:344-8
Stereotypic behavioral response of rat fetuses to acute hypoxia is altered by maternal alcohol consumption (Smotherman and Robinson). 1987;157:982-6

Fetal biophysical profile
Fetal assessment based on fetal biophysical profile scoring: experience in 19,221 referred high-risk pregnancies. II. An analysis of false-negative fetal deaths (Manning et al). 1987;157:880-4
The relationships among the fetal biophysical profile, umbilical cord pH, and Apgar scores (Vintzileos et al). 1987;157:627-31
The use of fetal biophysical profile improves pregnancy outcome in premature rupture of the membranes (Vintzileos et al). 1987;157:236-40

Fetal blood
In vitro training model for diagnostic and therapeutic fetal intravascular needle puncture (Timor-Tritsch and Yeh). 1987;157:858-9
Intrapartum use of fetal scalp hematocrit in the diagnosis of profound fetal anemia caused by fetomaternal hemorrhage (Herman et al). 1987;157:1182-3
Nifedipine: effects on fetal and maternal hemodynamics in pregnant sheep (Harake et al). 1987;157:1003-8
Percutaneous ultrasound-guided fetal blood sampling in the management of nonimmune hydrops fetalis (Hsieh et al). 1987;157:44-9
Scalp heat flux and its relationship to scalp blood pH of the fetus (Rudelstorfer et al). 1987;157:372-7
Validity of intrapartum diagnosis of fetal thrombocytopenia (Christiaens and Helmerhorst). 1987;157:864-5

Fetal death
Factors affecting psychological adjustment to a fetal death (Graham et al). 1987;157:254-7
Fetal death: diagnosis and management (Pitkin). 1987;157:583-9

Fetal distress
Antepartum predictors of fetal distress in postterm pregnancy (Bochner et al). 1987;157:353-8
Fetal monitoring during emergency obstetric transport (Elliott and Trujillo). 1987;157:245-7
Obstetric outcome of patients with a previous episode of spurious labor (Arulkumaran et al). 1987;157:17-20
A study on intrauterine fetal resuscitation with terbutaline (Patriarco et al). 1987;157:384-7

Fetal growth; *see also* **Intrauterine growth retardation**
Disruption of embryonic and fetal development due to preimplantation chemical insults: a critical review (Iannaccone et al). 1987;157:476-84 (Curr. dev.)
Soft tissue nuchal fold in the second-trimester fetus: standards for normal measurements compared with those in Down syndrome (Benacerraf and Frigoletto). 1987;157:1146-9
Sonographic amniotic fluid measurement and fetal growth retardation: a reappraisal (Patterson et al). 1987;157:1406-10
Sonographic features of the triploid fetus (Lockwood et al). 1987;157:285-7

Fetal hydrops; *see* **Hydrops fetalis**

Fetal lung maturity
Cholesteryl palmitate as a predictor of fetal lung maturity (Ludmir et al). 1987;157:84-8

Fetal pulmonary hypoplasia with hydrothorax (Murayama et al). 1987;157:119-20
Pleural effusions and pulmonary hypoplasia (Castillo et al). 1987;157:1252-5
Transplacental stimulation of functional and morphologic fetal rabbit lung maturation: effect of thyrotropin-releasing hormone (Devaskar et al). 1987;157:460-4
Ultrasonic ratio of fetal thoracic to abdominal circumference: an association with fetal pulmonary hypoplasia (Johnson et al). 1987;157:764-9

Fetal membranes
Amniotic fluid trypsin and premature rupture of membranes (McGregor et al) (Letter); (Kanayama) (Reply). 1987;157:1316-9
The effects of membrane permeability and binding by human serum proteins on steroid influx into the rabbit uterus (Steingold et al). 1987;157:1543-9
In vitro conversion of pregnenolone to progesterone in human term placenta and fetal membranes before and after onset of labor (Khan-Dawood). 1987;157:1333-7
Increased boy-to-girl ratio in women with preterm labor beginning with contractions (Seki and Kato) (Letter). 1987;157:215-6
Management of preterm premature rupture of membranes: lack of a national consensus (Capeless and Mead). 1987;157:11-2
The presence or absence of fetal breathing movements as a predictor of outcome in preterm labor (Besinger et al). 1987;157:753-7
A randomized trial of ritodrine tocolysis versus expectant management in patients with premature rupture of membranes at 25 to 30 weeks of gestation (Garite et al). 1987;157:388-93
Reduction of group B streptococcal maternal and neonatal infections in preterm pregnancies with premature rupture of membranes through a rapid identification test (Morales and Lim). 1987;157:13-6
Steroid synthetic and prostaglandin metabolizing activity is present in different cell populations from human fetal membranes and decidua (Challis and Vaughan). 1987;157:1474-81
Ultrasonic ratio of fetal thoracic to abdominal circumference: an association with fetal pulmonary hypoplasia (Johnson et al). 1987;157:764-9
The use of fetal biophysical profile improves pregnancy outcome in premature rupture of the membranes (Vintzileos et al). 1987;157:236-40

Fetal monitoring; *see also* **Acoustic stimulation**
Antepartum fetal surveillance in the patient with decreased fetal movement (Ahn et al). 1987;157:860-4
Breast stimulation test and oxytocin challenge test in fetal surveillance: a prospective randomized study (Lipitz et al). 1987;157:1178-81
Changes in intracardiac Doppler blood flow velocities in fetuses with absent umbilical artery diastolic flow (Reed et al). 1987;157:774-9
The effects of maternal ambulation on the nonstress test (Devoe et al). 1987;157:240-4
Fetal heart rate monitoring (Dawes and Redman) (Letter); (Fukushima et al) (Reply). 1987;157:513-4
Fetal heart rate response to vibratory acoustic stimulation predicts fetal pH in labor (Edersheim et al). 1987;157:1557-60
Fetal monitoring during emergency obstetric transport (Elliott and Trujillo). 1987;157:245-7
Heart rate variation and movement incidence in growth-retarded fetuses: the significance of antenatal late heart rate decelerations (Bekedam et al). 1987;157:126-33
Intrapartum electronic fetal monitoring efficacy (Fribourg) (Letter); (Thacker) (Reply). 1987;157:1013-4
Intrapartum vibratory acoustic stimulation of the human fetus during episodes of decreased heart rate variability (Divon et al). 1987;157:1355-8
Paper speed in electronic fetal heart rate monitoring (Floyd) (Letter); (Goodlin) (Reply). 1987;157:212
Patterns of human fetal heart rate accelerations from 26 weeks to term (Gagnon et al). 1987;157:743-8
Second-trimester fetal monitoring and preterm delivery in pregnancies with systemic lupus erythematosus and/or circulating anticoagulant (Druzin et al). 1987;157:1503-10
Umbilical blood waveforms in fetal surveillance of twins (Saldana et al). 1987;157:712-5

Fetal movement
Antepartum fetal surveillance in the patient with decreased fetal movement (Ahn et al). 1987;157:860-4
The effects of long-and short-term maternal caffeine ingestion on human fetal breathing and body movements in term gestations (McGowan et al). 1987;157:726-9
The immediate effects of chorionic villus sampling on fetal movements (Boogert et al). 1987;157:137-9
The length of the human umbilical cord in twin pregnancies (Soernes and Bakke). 1987;157:1229-30
The presence or absence of fetal breathing movements as a predictor of outcome in preterm labor (Besinger et al). 1987;157:753-7
The use of fetal neuromuscular blockade during intrauterine procedures (Moise et al). 1987;157:874-9

Fetomaternal hemorrhage
Fetal death: diagnosis and management (Pitkin). 1987;157:583-9
Intrapartum use of fetal scalp hematocrit in the diagnosis of profound fetal anemia caused by fetomaternal hemorrhage (Herman et al). 1987;157:1182-3
Ultrasound diagnosis of abruptio placentae with fetomaternal hemorrhage (Cardwell). 1987;157:358-9

Fetoplacental blood
Hypoxia-induced fetoplacental vasoconstriction in perfused human placental cotyledons (Howard et al). 1987;157:1261-6
Measurement of human fetoplacental blood volume in erythroblastosis fetalis (Nicolaides et al). 1987;157:50-3

α-Fetoprotein
Amniotic fluid α-fetoprotein levels and pregnancy outcome (Brumfield et al). 1987;157:822-5
Elevated maternal serum α-fetoprotein levels and oligohydramnios: poor prognosis for pregnancy outcome (Dyer et al). 1987;157:336-9
Maternal serum α-fetoprotein screening: effects of weight adjustment (Kazazian et al) (Letter); (Macri et al) (Reply). 1987;157:782-4
Maternal serum α-fetoprotein screening. III. Pitfalls in evaluating black gravid women (Macri et al). 1987;157:820-2
Outcome in patients with unusually high maternal serum α-fetoprotein levels (Nelson et al). 1987;157:572-6

Fetus
Acute atherosis in preeclampsia: maternal determinants and fetal outcome in the presence of the lesion (Khong et al). 1987;157:360-3
Acute oligohydramnios in postdate pregnancy (Clement et al). 1987;157:884-6

The binding and metabolism of low-density lipoprotein by skin fibroblasts of fetuses and newborns with anencephaly (Carr and Parker). 1987;157:1351-5
Breakage of a fetal scalp blade with retention of fragments in the infant's scalp (Nieburg and Gross). 1987;157:441-2
Cerebral oxidative metabolism in fetal sheep with multiple-dose ethanol infusion (Richardson et al). 1987;157:1496-502
Cord sampling for the evaluation of oxygenation and acid-base balance in human growth-retarded fetuses (Pardi et al). 1987;157:1221-8
Changes in intracardiac Doppler blood flow velocities in fetuses with absent umbilical artery diastolic flow (Reed et al). 1987;157:774-9
Digoxin-like immunoreactive substance in fetuses with and without cardiac pathology (Weiner et al). 1987;157:368-71
Drug accumulation in lung fluid of the fetal lamb after maternal or fetal administration (Riggs et al). 1987;157:1286-91
The effect of severing the spinal cord of fetal lambs on length of gestation (Nowak et al). 1987;157:464-7
The effect of smoking on placental and fetal zinc status (Kuhnert et al). 1987;157:1241-6
Effects of calcium entry blocker (nicardipine) tocolysis in rhesus macaques: fetal plasma concentrations and cardiorespiratory changes (Ducsay et al). 1987;157:1482-6
Effects of cochlear ablation on local cerebral glucose utilization in fetal sheep (Abrams et al). 1987;157:1438-42
The effects of long-and short-term maternal caffeine ingestion on human fetal breathing and body movements in term gestations (McGowan et al). 1987;157:726-9
Effects of maternal glucose infusion on fetal acid-base status in human pregnancy (Philipson et al). 1987;157:866-73
Effects of norepinephrine on lung fluid flow rate in the chronically catheterized fetal lamb (Higuchi et al). 1987;157:986-90
Erb's palsy and fetal bruising after external cephalic version: case report (Petrikovsky et al). 1987;157:258
Fetal echocardiographic screening for congenital heart disease: the importance of the four-chamber view (Copel et al). 1987;157:648-55
Fetal umbilical artery flow velocimetry in postdate pregnancies (Guidetti et al). 1987;157:1521-3
Fetal weight estimation formulas with head, abdominal, femur, and thigh circumference measurements (Vintzileos et al). 1987;157:410-4
Fetal-induced trauma as a cause of antepartum hemorrhage (Eden). 1987;157:830-1
Formulas for fetal weight estimation by ultrasound measurements based on neonatal specific gravities and volumes (Shinozuka et al). 1987;157:1140-5
Human fetal breathing response to intravenous glucose is directly related to gestational age (Harper et al). 1987;157:1403-5
Increased boy-to-girl ratio in women with preterm labor beginning with contractions (Seki and Kato) (Letter). 1987;157:215-6
Insufficient transplacental digoxin transfer in severe hydrops fetalis (Younis and Granat). 1987;157:1268-9
Local cerebral glucose utilization in fetal sheep exposed to noise (Abrams et al). 1987;157:456-60
Metabolism of lipoproteins by human fetal hepatocytes (Carr). 1987;157:1338-44
The nonpredictive value of fetal urinary electrolytes: preliminary report of outcomes and correlation with pathologic diagnosis (Wilkins et al). 1987;157:694-8
Pemphigus in pregnancy: a reevaluation of fetal risk (Metzker and Merlob) (Letter). 1987;157:1012-3
Percutaneous umbilical transfusion in severe rhesus isoimmunization: resolution of fetal hydrops (Socol et al). 1987;157:1369-75
Pleural effusions and pulmonary hypoplasia (Castillo et al). 1987;157:1252-5
Pregnancy outcome in medically complicated and uncomplicated patients aged 40 years or older (Lehmann and Chism). 1987;157:738-42
The pregnant brain dead and the fetus: Must we always try to wrest life from death? (Loewy). 1987;157:1097-101 (Clin. opinion)
The presence or absence of fetal breathing movements as a predictor of outcome in preterm labor (Besinger et al). 1987;157:753-7
The relationship between cadmium, zinc, and birth weight in pregnant women who smoke (Kuhnert et al). 1987;157:1247-51
Spontaneous fetal seizures in utero (Maouris) (Letter). 1987;157:1009-10
A study on intrauterine fetal resuscitation with terbutaline (Patriarco et al). 1987;157:384-7
Successful fetal therapy for cystic adenomatoid malformation associated with second-trimester hydrops (Clark et al). 1987;157:294-5
Ultrasonic prediction of birth weight in preterm fetuses: Which formula is best? (Pielet et al). 1987;157:1411-4
Ultrasound evaluation of tachycardia-induced hydrops in the fetal lamb (Nimrod et al). 1987;157:655-9
The use of fetal neuromuscular blockade during intrauterine procedures (Moise et al). 1987;157:874-9
Vasopressin-induced bradycardia in fetal and adult sheep is not dependent on an increase in blood pressure (Harper and Rose). 1987;157:448-53

Fever

Careful surgical technique can reduce infectious morbidity after cesarean section (Lyon and Richardson). 1987;157:557-62
The normal parturient's admission temperature (Acker et al). 1987;157:308-11

Fibroblast

The binding and metabolism of low-density lipoprotein by skin fibroblasts of fetuses and newborns with anencephaly (Carr and Parker). 1987;157:1351-5

Fibronectin

Mechanisms for reduced colloid osmotic pressure in preeclampsia (Bhatia et al). 1987;157:106-8
Preeclampsia, delivery, and the hemostatic system (Saleh et al). 1987;157:331-6

Fine needle aspiration

Cervical endometriosis: facilitated diagnosis by fine needle aspiration cytologic testing (Veiga-Ferreira et al). 1987;157:849-56

Follicle-stimulating hormone

Follicle-stimulating hormone is the main determinant of follicular recruitment and development in ovulation induction with human menopausal gonadotropin (Vermesh and Kletzky). 1987;157:1397-402

Follicular fluid

Proopiomelanocortin-related peptides and methionine enkephalin in human follicular fluid: changes during the menstrual cycle (Petraglia et al). 1987;157:142-6

Freezing of embryo
Human embryo viability related to freezing and thawing procedures (Testart et al). 1987;157:168-71
Fungal infection
Mycotic aneurysms in pregnancy (Boike et al). 1987;157:340-1

G

Galactography
Breast galactography in the treatment of infected cysts (Tihansky and DiBlasio). 1987;157:1278-80
GBS-Test
A screening test (GBS-Test) for urogenital carriage of group B streptococci (Christensen and Christensen). 1987;157:341-2
Genetics
Genetic heterogeneity of prematurity and intrauterine growth retardation: clues from the Old Order Amish (Khoury and Cohen). 1987;157:400-10
Restriction fragment length polymorphisms of the insulin gene hypervariable region in gestational onset diabetes mellitus (Ober et al). 1987;157:1364-8
Gestation length
The effect of severing the spinal cord of fetal lambs on length of gestation (Nowak et al). 1987;157:464-7
Gestational age
Human fetal breathing response to intravenous glucose is directly related to gestational age (Harper et al). 1987;157:1403-5
Patterns of human fetal heart rate accelerations from 26 weeks to term (Gagnon et al). 1987;157:743-8
Gestational diabetes mellitus; *see* **Diabetes mellitus**
Gestational trophoblastic disease
Treatment of nonmetastatic gestational trophoblastic disease with oral methotrexate (Barter et al). 1987;157:1166-8
Gestodene
New progestogens in oral contraceptives (Runnebaum and Rabe). 1987;157:1059-63
Gestrinone
The morphologic effect of short-term medical therapy of endometriosis (Brosens et al). 1987;157:1215-21
Glucocorticoids
Prevention of pelvic adhesion formation by different modalities of treatment (Fayez and Schneider). 1987;157:1184-8
Glucose; *see also* **Diabetes mellitus**
The effect of mild hypoxemia maintained for twenty-four hours on maternal and fetal glucose, lactate, cortisol, and arginine vasopressin in pregnant sheep at 122 to 139 days' gestation (Towell et al). 1987;157:1550-7
Effects of cochlear ablation on local cerebral glucose utilization in fetal sheep (Abrams et al). 1987;157:1438-42
Effects of maternal glucose infusion on fetal acid-base status in human pregnancy (Philipson et al). 1987;157:866-73
Human fetal breathing response to intravenous glucose is directly related to gestational age (Harper et al). 1987;157:1403-5
Local cerebral glucose utilization in fetal sheep exposed to noise (Abrams et al). 1987;157:456-60
Verified self-monitored blood glucose data versus glycosylated hemoglobin and glycosylated serum protein as a means of predicting short-and long-term metabolic control in gestational diabetes (Brustman et al). 1987;157:699-703
Glucose tolerance
The "breakfast tolerance test": screening for gestational diabetes with a standardized mixed nutrient meal (Coustan et al). 1987;157:1113-7
Chronic oral terbutaline tocolytic therapy is associated with maternal glucose intolerance (Main et al). 1987;157:644-7
Effect of chronically elevated androgen or estrogen on the glucose tolerance test and insulin response in female rhesus monkeys (Billiar et al). 1987;157:1297-302
Influence of the menstrual cycle on glucose tolerance and insulin secretion (Bonora et al). 1987;157:140-1
Metabolic effects of oral contraceptives (Gaspard). 1987;157:1029-41
The significance of one abnormal glucose tolerance test value on adverse outcome in pregnancy (Langer et al). 1987;157:758-63
Glucuronide
Natural family planning (Brown et al). 1987;157:1082-9
γ-Glutamyl transferase
γ-Glutamyl transferase and mean cell volume reveal maternal alcohol abuse and fetal alcohol effects (Ylikorkala et al). 1987;157:344-8
Glycolysis
Placental glycolysis and energy metabolism in preeclampsia (Bloxam et al). 1987;157:97-101
Glycosylation
Gestational diabetes: maternal response to diet and insulin therapy as reflected by glycosylated hemoglobin concentration (Grandis et al). 1987;157:1118-21
Verified self-monitored blood glucose data versus glycosylated hemoglobin and glycosylated serum protein as a means of predicting short-and long-term metabolic control in gestational diabetes (Brustman et al). 1987;157:699-703
Gonadotropins
Age-related changes in the female hormonal environment during reproductive life (Musey et al). 1987;157:312-7
First-trimester serum levels of the β-subunit of human chorionic gonadotropin in a tubal molar pregnancy (Chase et al). 1987;157:910
Follicle-stimulating hormone is the main determinant of follicular recruitment and development in ovulation induction with human menopausal gonadotropin (Vermesh and Kletzky). 1987;157:1397-402
Human chorionic gonadotropin, estriol, and testosterone changes in two pregnancies with hyperreactio luteinalis (Muechler et al). 1987;157:1126-8
Insulin resistance and abnormal ovarian responses to human chorionic gonadotropin in chronically anovulatory women (Kustin et al). 1987;157:1468-73
Modulating actions of estradiol on gonadotropin-releasing hormone–stimulated prolactin secretion in postmenopausal individuals (Christiansen et al). 1987;157:320-5
Observations on the log human chorionic gonadotropin–time relationship in early pregnancy and its practical implications (Kadar and Romero). 1987;157:73-8
Recent developments in immunocontraception (Talwar and Gaur). 1987;157:1075-8
Gossypol
Experiences with gossypol as a male pill (Liu et al). 1987;157:1079-81
Gram stains
The use and limitations of endocervical Gram stains and mucopurulent cervicitis as predictors for *Chlamydia tra-*

chomatis in female adolescents (Moscicki et al). 1987;157:65-71

Grief

Evaluation of a perinatal grief support team (Lake et al). 1987;157:1203-6

Growth; *see* **Fetal growth; Intrauterine growth retardation**

Growth hormone

Growth hormone, somatomedin C, and nonsuppressible insulin-like activity levels compared in premature, small, average birth weight, and large infants (Samaan et al). 1987;157:1524-8

In vivo and in vitro modulation of growth hormone and prolactin of a mixed somatotropic-lactotropic pituitary microadenoma (Muechler et al). 1987;157:453-5

Gynecology

Mechanical intestinal obstruction in patients with gynecologic disease: a review of 368 patients (Krebs and Goplerud). 1987;157:577-83

Urogynecology: comments and caveats (Thiede and Saini). 1987;157:563-8

H

Haemophilus influenzae

Haemophilus influenzae infection and midtrimester abortion (Amstey and Ogden) (Letter). 1987;157:518

Handedness

The umbilical cord twist: origin, direction, and relevance (Lacro et al). 1987;157:833-8

Haptoglobin

Haptoglobin helps diagnose the HELLP syndrome (Poldre). 1987;157:1267

Head circumference

Fetal weight estimation formulas with head, abdominal, femur, and thigh circumference measurements (Vintzileos et al). 1987;157:410-4

Heart block

Congenital heart block and cardiac anomalies in the absence of maternal connective tissue disease (Shenker et al). 1987;157:248-53

Heart disease

Fetal echocardiographic screening for congenital heart disease: the importance of the four-chamber view (Copel et al). 1987;157:648-55

Heart rate; *see* **Fetal monitoring**

Heat flux

Scalp heat flux and its relationship to scalp blood pH of the fetus (Rudelstorfer et al). 1987;157:372-7

HELLP syndrome

Haptoglobin helps diagnose the HELLP syndrome (Poldre). 1987;157:1267

HELLP syndrome (Gerace) (Letter); (Sibai) (Reply). 1987;157:1015-6

Hemarthrosis

Factor XI deficiency presenting as hemarthrosis during pregnancy (Musclow et al). 1987;157:178-9

Hemifacial microsomia

Possible vascular disruptive origin of hemifacial microsomia? (Schinzel) (Letter). 1987;157:1319

Hemodynamics

Nifedipine: effects on fetal and maternal hemodynamics in pregnant sheep (Harake et al). 1987;157:1003-8

Hemoglobin

Intrapartum use of fetal scalp hematocrit in the diagnosis of profound fetal anemia caused by fetomaternal hemorrhage (Herman et al). 1987;157:1182-3

Verified self-monitored blood glucose data versus glycosylated hemoglobin and glycosylated serum protein as a means of predicting short-and long-term metabolic control in gestational diabetes (Brustman et al). 1987;157:699-703

Hemolysis

The origin of increased serum iron in pregnancy-induced hypertension (Samuels et al). 1987;157:721-5

Haptoglobin helps diagnose the HELLP syndrome (Poldre). 1987;157:1267

HELLP syndrome (Gerace) (Letter); (Sibai) (Reply). 1987;157:1015-6

Hemolytic disease of newborn; *see also* **Hydrops fetalis**

Percutaneous umbilical transfusion in severe rhesus isoimmunization: resolution of fetal hydrops (Socol et al). 1987;157:1369-75

Hemorrhage; *see also* **Bleeding**

Fetal death: diagnosis and management (Pitkin). 1987;157:583-9

Fetal-induced trauma as a cause of antepartum hemorrhage (Eden). 1987;157:830-1

Intrapartum use of fetal scalp hematocrit in the diagnosis of profound fetal anemia caused by fetomaternal hemorrhage (Herman et al). 1987;157:1182-3

Status of infants at birth and risk for adverse neonatal events and long-term sequelae: a study in low birth weight infants (Luthy et al). 1987;157:676-9

Ultrasound diagnosis of abruptio placentae with fetomaternal hemorrhage (Cardwell). 1987;157:358-9

Hemostasis

Preeclampsia, delivery, and the hemostatic system (Saleh et al). 1987;157:331-6

Henoch-Schönlein purpura

Pregnancy in Henoch-Schönlein purpura (Joseph et al). 1987;157:911-2

Heparin

Prevention of pelvic adhesion formation by different modalities of treatment (Fayez and Schneider). 1987;157:1184-8

Hepatocyte

Metabolism of lipoproteins by human fetal hepatocytes (Carr). 1987;157:1338-44

Hermaphrodite

The endocrinologic evaluation of a 45,X true hermaphrodite (Rosen et al). 1987;157:1272-3

Herpes simplex

Labial agglutination secondary to herpes simplex II infection (DeMarco et al). 1987;157:296-7

High-risk pregnancy; *see also* **Fetal biophysical profile**

Fetal assessment based on fetal biophysical profile scoring: experience in 19,221 referred high-risk pregnancies. II. An analysis of false-negative fetal deaths (Manning et al). 1987;157:880-4

Hirsutism

The endocrinologic evaluation of a 45,X true hermaphrodite (Rosen et al). 1987;157:1272-3

Histology

Histologic composition of endometrial carcinomas analyzed for steroid receptor content (Soper et al). 1987;157:26-7

HLA antigen; *see* **Human leukocyte antigen**

Homozygous α-thalassemia

Theca-lutein ovarian cysts associated with homozygous α-thalassemia (Miller et al). 1987;157:912-4

Hormone replacement therapy

In vivo and in vitro modulation of growth hormone and

prolactin of a mixed somatotropic-lactotropic pituitary microadenoma (Muechler et al). 1987;157:453-5
Modulating actions of estradiol on gonadotropin-releasing hormone–stimulated prolactin secretion in postmenopausal individuals (Christiansen et al). 1987;157:320-5

Hormones
Age-related changes in the female hormonal environment during reproductive life (Musey et al). 1987;157:312-7
Circulating neurohypophyseal hormones in anencephalic infants (Oosterbaan and Swaab). 1987;157:117-9
Preliminary observations on lactoferrin secretion in human vaginal mucus: variation during the menstrual cycle, evidence of hormonal regulation, and implications for infection with *Neisseria gonorrhoeae* (Cohen et al). 1987;157:1122-5
Transplacental stimulation of functional and morphologic fetal rabbit lung maturation: effect of thyrotropin-releasing hormone (Devaskar et al). 1987;157:460-4

Human chorionic gonadotropin; *see* **Gonadotropins**

Human immunodeficiency virus
Isolation of acquired immunodeficiency syndrome virus from the placenta (Hill et al). 1987;157:10-1

Human leukocyte antigen
HLA antigen expression and induction by γ-interferon in cultured human trophoblasts (Feinman et al). 1987;157:1429-34
Human leukocyte antigen associated with endometrial carcinoma with a new classification of endometrial carcinoma based on its etiology (Kanuma and Igarashi). 1987;157:427-32
Recurrent spontaneous abortion and human leukocyte antigen DRwB (Takamizawa et al) (Letter). 1987;157:514-5

Human menopausal gonadotropin
Follicle-stimulating hormone is the main determinant of follicular recruitment and development in ovulation induction with human menopausal gonadotropin (Vermesh and Kletzky). 1987;157:1397-402

Hyaline membrane disease
Cholesteryl palmitate as a predictor of fetal lung maturity (Ludmir et al). 1987;157:84-8
Review of causes of perinatal mortality in a regional perinatal center, 1980 to 1984 (Ohlsson et al). 1987;157:443-5
Transplacental stimulation of functional and morphologic fetal rabbit lung maturation: effect of thyrotropin-releasing hormone (Devaskar et al). 1987;157:460-4

Hydatidiform mole
Hydatidiform mole: cytogenetically unusual cases and their implications for the present classification (Vejerslev et al). 1987;157:180-4 (Curr. dev.)
Partial hydatidiform moles: deoxyribonucleic acid content and course (David et al). 1987;157:969-73

Hydramnios
Genetic implications of idiopathic hydramnios (Landy et al). 1987;157:114-7

Hydronephrosis
The nonpredictive value of fetal urinary electrolytes: preliminary report of outcomes and correlation with pathologic diagnosis (Wilkins et al). 1987;157:694-8
Renal arterial blood flow velocity waveforms in pregnant women (Hata et al). 1987;157:1269-71

Hydrops fetalis
Insufficient transplacental digoxin transfer in severe hydrops fetalis (Younis and Granat). 1987;157:1268-9
Percutaneous ultrasound-guided fetal blood sampling in the management of nonimmune hydrops fetalis (Hsieh et al). 1987;157:44-9
Percutaneous umbilical transfusion in severe rhesus isoimmunization: resolution of fetal hydrops (Socol et al). 1987;157:1369-75
Successful fetal therapy for cystic adenomatoid malformation associated with second-trimester hydrops (Clark et al). 1987;157:294-5
Ultrasound evaluation of tachycardia-induced hydrops in the fetal lamb (Nimrod et al). 1987;157:655-9

Hydrostatic pressure
Calculated capillary hydrostatic pressure in normal pregnancy and preeclampsia (Øian and Maltau). 1987;157:102-6

Hydrothorax
Fetal pulmonary hypoplasia with hydrothorax (Murayama et al). 1987;157:119-20

Hymen
Configuration of the prepubertal hymen (Pokorny). 1987;157:950-6

Hyperimmunoglobulinemia E
Hyperimmunoglobulinemia E and pregnancy: a case report (Lindenbaum et al). 1987;157:1273-4

Hyperprolactinemia
Evidence that estrogen may be a key factor in hyperprolactinemic anovulation: a case report (Sakamoto et al). 1987;157:318-9

Hyperreactio luteinalis
Human chorionic gonadotropin, estriol, and testosterone changes in two pregnancies with hyperreactio luteinalis (Muechler et al). 1987;157:1126-8

Hypertension; *see also* **Blood pressure**
Beneficial effects of U-63,557A, a thromboxane synthetase inhibitor, in an ovine model of pregnancy-induced hypertension (Keith et al). 1987;157:199-203
A classification of hypertension in pregnancy based on Doppler velocimetry (Ducey et al). 1987;157:680-5
Hypertensive diseases of pregnancy: nulliparity, primiparity, multiparity, and gravidity (Reamy) (Letter); (Gleicher) (Reply). 1987;157:1012
Increased fetoplacental active renin production in pregnancy-induced hypertension (Brar et al). 1987;157:363-7
The origin of increased serum iron in pregnancy-induced hypertension (Samuels et al). 1987;157:721-5

Hypoglycemia
Hypoglycemia: How little is too much for the embryo? (Sadler and Hunter). 1987;157:190-3

Hypokalemia
Experiences with gossypol as a male pill (Liu et al). 1987;157:1079-81

Hypoplasia; *see* **Pulmonary hypoplasia**

Hypotension
Profound hypotension complicating magnesium therapy (Frohlich) (Letter). 1987;157:513

Hypoxemia; *see also* **Hypoxia**
The effect of mild hypoxemia maintained for twenty-four hours on maternal and fetal glucose, lactate, cortisol, and arginine vasopressin in pregnant sheep at 122 to 139 days' gestation (Towell et al). 1987;157:1550-7

Hypoxia; *see also* **Hypoxemia**
Hypoxia-induced fetoplacental vasoconstriction in perfused human placental cotyledons (Howard et al). 1987;157:1261-6

Stereotypic behavioral response of rat fetuses to acute hypoxia is altered by maternal alcohol consumption (Smotherman and Robinson). 1987;157:982-6

Hyskon
Prevention of pelvic adhesion formation by different modalities of treatment (Fayez and Schneider). 1987;157:1184-8

Hysterectomy
Single-dose prophylaxis for vaginal and abdominal hysterectomy (Hemsell et al). 1987;157:498-501

Hysterosalpingogram
Hysterosalpingographic evaluation of tubal patency after ectopic pregnancy (Mitchell et al). 1987;157:618-22

I

Ibuprofen
Cyclooxygenase inhibition reduces placental transfer: reversal by carbacyclin (Kuhn and Stuart). 1987;157:194-8

Idiopathic thrombocytopenic purpura
Validity of intrapartum diagnosis of fetal thrombocytopenia (Christiaens and Helmerhorst). 1987;157:864-5

Iliohypogastric nerve
Nerve entrapment after Pfannenstiel incision (Sippo et al). 1987;157:420-1

Imaging; *see also* **Magnetic resonance imaging; Ultrasound**
Diagnostic imaging of gynecologic tumors with the monoclonal antibody 791T/36 (Powell et al). 1987;157:28-34

Immunization
Recent developments in immunocontraception (Talwar and Gaur). 1987;157:1075-8
Varicella zoster antibody testing in the care of pregnant women exposed to varicella (McGregor et al). 1987;157:281-4

Immunoassay
Natural family planning (Brown et al). 1987;157:1082-9

Immunocontraception
Recent developments in immunocontraception (Talwar and Gaur). 1987;157:1075-8

Immunofluorescence
Detection of *Chlamydia trachomatis* cervical infection: a comparison of Papanicolaou and immunofluorescent staining with cell culture (Quinn et al). 1987;157:394-9

Immunoglobulin E
Hyperimmunoglobulinemia E and pregnancy: a case report (Lindenbaum et al). 1987;157:1273-4

Immunoglobulin M
A pregnant woman with a high level of naturally occurring immunoglobulin M antibodies to *Toxoplasma gondii* (Konishi). 1987;157:832-3

Immunohistochemistry
Adenosquamous carcinoma of the fallopian tube: a clinicopathologic case report with verification of the diagnosis by immunohistochemical and ultrastructural studies (Moore et al). 1987;157:903-5
Endometrial adenocarcinoma estrogen receptor content: association of clinicopathologic features with immunohistochemical analysis compared with standard biochemical methods (Mutch et al). 1987;157:924-31
Ovarian prostaglandin synthase: immunohistochemical localization in the rat (Curry et al). 1987;157:537-43

Immunoreactivity
Digoxin-like immunoreactive substance in fetuses with and without cardiac pathology (Weiner et al). 1987;157:368-71
Digoxin-like immunoreactive substance in pregnancy (Gonzalez et al). 1987;157:660-4

Immunosuppression
Suppression of lymphocyte reactivity in vitro by supernatants of explants of human endometrium (Wang et al). 1987;157:956-63

Implantation
Disruption of embryonic and fetal development due to preimplantation chemical insults: a critical review (Iannaccone et al). 1987;157:476-84 (Curr. dev.)

In vitro fertilization; *see* **Fertilization**

Incompetent cervix
Decreased elastic fibers and desmosine content in incompetent cervix (Leppert et al). 1987;157:1134-9
Management of the diethylstilbestrol-exposed pregnant patient: a prospective study (Ludmir et al). 1987;157:665-9

Incontinence
Urogynecology: comments and caveats (Thiede and Saini). 1987;157:563-8

Indomethacin
Cyclooxygenase inhibition reduces placental transfer: reversal by carbacyclin (Kuhn and Stuart). 1987;157:194-8
Treatment of polyhydramnios with prostaglandin synthetase inhibitor (indomethacin) (Cabrol et al). 1987;157:422-6

Infection
Arachidonate lipoxygenase metabolites in amniotic fluid of women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1454-60
Breast galactography in the treatment of infected cysts (Tihansky and DiBlasio). 1987;157:1278-80
Careful surgical technique can reduce infectious morbidity after cesarean section (Lyon and Richardson). 1987;157:557-62
Changing concepts in obstetric antibiotic prophylaxis (Galask). 1987;157:491-7
Colposcopic correlates of cervical papillomavirus infection (Follen et al). 1987;157:809-14
Correlation between chlamydia infection and clinical evaluation, vaginal wet smear, and cervical swab test in female adolescents (Thejls et al). 1987;157:974-6
Cost-effective use of antibiotic prophylaxis for cesarean section (Ford et al). 1987;157:506-10
Detection of *Chlamydia trachomatis* cervical infection: a comparison of Papanicolaou and immunofluorescent staining with cell culture (Quinn et al). 1987;157:394-9
Haemophilus influenzae infection and midtrimester abortion (Amstey and Ogden) (Letter). 1987;157:518
Infection and labor: the detection of endotoxin in amniotic fluid (Romero et al). 1987;157:815-9
Labial agglutination secondary to herpes simplex II infection (DeMarco et al). 1987;157:296-7
Necrotizing fasciitis of the vulva (Roberts). 1987;157:568-71
Preliminary observations on lactoferrin secretion in human vaginal mucus: variation during the menstrual cycle, evidence of hormonal regulation, and implications for infection with *Neisseria gonorrhoeae* (Cohen et al). 1987;157:1122-5
Prostaglandin concentrations in amniotic fluid of women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1461-7
Reduction of group B streptococcal maternal and neonatal infections in preterm pregnancies with premature rupture of membranes through a rapid identification test (Morales and Lim). 1987;157:13-6

Review of causes of perinatal mortality in a regional perinatal center, 1980 to 1984 (Ohlsson et al). 1987;157:443-5
A screening test (GBS-Test) for urogenital carriage of group B streptococci (Christensen and Christensen). 1987;157:341-2
Single-agent therapy for women with acute polymicrobial pelvic infections (Hemsell et al). 1987;157:488-90
Single-dose prophylaxis for vaginal and abdominal hysterectomy (Hemsell et al). 1987;157:498-501
Single-dose versus multiple-dose piiperacillin prophylaxis in primary cesarean operation (Gall and Hill). 1987;157:502-6
Symposium on infection: a complication of obstetric and gynecologic surgery. 1987;157:485-512
Symposium on infection: a complication of obstetric and gynecologic surgery: questions from the audience. 1987;157:511-2
Treatment and prevention of female pelvic infection: the quest for single-agent therapy (Cunningham). 1987;157:485-8
The use and limitations of endocervical Gram stains and mucopurulent cervicitis as predictors for *Chlamydia trachomatis* in female adolescents (Moscicki et al). 1987;157:65-71

Infertility; *see also* **Fertilization**
Contraceptive use, pelvic inflammatory disease, and fertility problems among American women: 1982 (Aral et al). 1987;157:59-64
Local peritoneal factors: their role in infertility associated with endometriosis (Awadalla et al). 1987;157:1207-14
The morphologic effect of short-term medical therapy of endometriosis (Brosens et al). 1987;157:1215-21
Prevention of pelvic adhesion formation by different modalities of treatment (Fayez and Schneider). 1987;157:1184-8
Primary cesarean section and subsequent fertility (LaSala and Berkeley). 1987;157:379-83
Seminal plasma proteins of fertile and infertile men analyzed by two-dimensional electrophoresis (Ayyagari et al). 1987;157:1528-33

Inositol trisphosphate
A new look at uterine muscle contraction (Carsten and Miller). 1987;157:1303-15 (Curr. dev.)

Insulin; *see also* **Diabetes mellitus**
Effect of chronically elevated androgen or estrogen on the glucose tolerance test and insulin response in female rhesus monkeys (Billiar et al). 1987;157:1297-302
The effect of insulin on aromatase activity in isolated human endometrial glands and stroma (Randolph et al). 1987;157:1534-9
Gestational diabetes: insulin requirements in pregnancy (Langer et al). 1987;157:669-75
Gestational diabetes: maternal response to diet and insulin therapy as reflected by glycosylated hemoglobin concentration (Grandis et al). 1987;157:1118-21
Growth hormone, somatomedin C, and nonsuppressible insulin-like activity levels compared in premature, small, average birth weight, and large infants (Samaan et al). 1987;157:1524-8
Influence of the menstrual cycle on glucose tolerance and insulin secretion (Bonora et al). 1987;157:140-1
Insulin resistance and abnormal ovarian responses to human chorionic gonadotropin in chronically anovulatory women (Kustin et al). 1987;157:1468-73
Postprandial walking exercise in pregnant insulin-dependent (type 1) diabetic women: reduction of plasma lipid levels but absence of a significant effect on glycemic control (Hollingsworth and Moore). 1987;157:1359-63
Restriction fragment length polymorphisms of the insulin gene hypervariable region in gestational onset diabetes mellitus (Ober et al). 1987;157:1364-8

γ-Interferon
HLA antigen expression and induction by γ-interferon in cultured human trophoblasts (Feinman et al). 1987;157:1429-34

Interleukins
Enhancement of maternal and neonatal natural killer cell activity with interleukin-2 (Baker et al). 1987;157:780-1
Local peritoneal factors: their role in infertility associated with endometriosis (Awadalla et al). 1987;157:1207-14

Intestinal obstruction
Mechanical intestinal obstruction in patients with gynecologic disease: a review of 368 patients (Krebs and Goplerud). 1987;157:577-83

Intracranial hemorrhage
Status of infants at birth and risk for adverse neonatal events and long-term sequelae: a study in low birth weight infants (Luthy et al). 1987;157:676-9

Intraepithelial neoplasia; *see* **Cervical intraepithelial neoplasia**

Intrapartum fetal monitoring; *see* **Fetal monitoring**

Intrauterine device
Contraception: an overview (Hammerstein). 1987;157:1020-3

Intrauterine fetal resuscitation
A study on intrauterine fetal resuscitation with terbutaline (Patriarco et al). 1987;157:384-7

Intrauterine growth retardation; *see also* **Fetal growth**
Caffeine-cigarette interaction on fetal growth (Beaulac-Baillargeon and Desrosiers). 1987;157:1236-40
Chorionic villus sampling is associated with normal fetal growth (Williams et al). 1987;157:708-12
Cord sampling for the evaluation of oxygenation and acid-base balance in human growth-retarded fetuses (Pardi et al). 1987;157:1221-8
Fetal cerebellar growth unaffected by intrauterine growth retardation: a new parameter for prenatal diagnosis (Reece et al). 1987;157:632-8
Fetal growth retardation as a complication of pregnancy in patients with neurofibromatosis (Blickstein and Lancet). 1987;157:343
Formulas for fetal weight estimation by ultrasound measurements based on neonatal specific gravities and volumes (Shinozuka et al). 1987;157:1140-5
Genetic heterogeneity of prematurity and intrauterine growth retardation: clues from the Old Order Amish (Khoury and Cohen). 1987;157:400-10
Heart rate variation and movement incidence in growth-retarded fetuses: the significance of antenatal late heart rate decelerations (Bekedam et al). 1987;157:126-33
In utero ponderal index as a prognostic factor in the evaluation of intrauterine growth retardation (Yagel et al). 1987;157:415-9
Neonatal morphometrics and perinatal outcome: Who is growth retarded? (Patterson and Pouliot). 1987;157:691-3
Pregnancy among obstetricians: a comparison of births before, during, and after residency (Grunebaum et al). 1987;157:79-83

Prevention of recurrent idiopathic fetal growth retardation by low-dose aspirin and dipyridamole (Wallenburg and Rotmans). 1987;157:1230-5
Recurrent small for gestational age birth: perinatal risks and outcomes (Wolfe et al). 1987;157:288-93
The relationship between cadmium, zinc, and birth weight in pregnant women who smoke (Kuhnert et al). 1987;157:1247-51
Sonographic amniotic fluid measurement and fetal growth retardation: a reappraisal (Patterson et al). 1987;157:1406-10

Intrauterine pressure
Simultaneous objective and subjective evaluation of meclofenamate sodium in the treatment of primary dysmenorrhea (Smith and Powell). 1987;157:611-8

Intrauterine procedures; *see also specific procedure*
The use of fetal neuromuscular blockade during intrauterine procedures (Moise et al). 1987;157:874-9
Technical aspects of intravascular intrauterine transfusions: lessons learned from thirty-three procedures (Berkowitz et al). 1987;157:4-9 (Clin. opinion)

Intravascular needle puncture
In vitro training model for diagnostic and therapeutic fetal intravascular needle puncture (Timor-Tritsch and Yeh). 1987;157:858-9

Involution
Abdominal pregnancy: magnetic resonance identification with ultrasonographic follow-up of placental involution (Spanta et al). 1987;157:887-9

Iron
The origin of increased serum iron in pregnancy-induced hypertension (Samuels et al). 1987;157:721-5
Red blood cell zinc protoporphyrin testing for iron-deficiency anemia in pregnancy (Schifman et al). 1987;157:304-7

Isoimmunization; *see also* **Hydrops fetalis**
Percutaneous umbilical transfusion in severe rhesus isoimmunization: resolution of fetal hydrops (Socol et al). 1987;157:1369-75

Items
Items. 1987;157:228, 520, 788, 1018, 1324, 1562

K

Karyotype
Fetal death: diagnosis and management (Pitkin). 1987;157:583-9
First-trimester vaginal bleeding and the loss of chromosomally normal and abnormal conceptions (Strobino and Pantel-Silverman). 1987;157:1150-4

L

Labial agglutination
Labial agglutination secondary to herpes simplex II infection (DeMarco et al). 1987;157:296-7

Labor; *see also* **Labor, premature; Labor complications**
Estrogen, progesterone, prolactin, prostaglandin E_2, prostaglandin $F_{2\alpha}$, 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$, and 6-keto-prostaglandin $F_{1\alpha}$ gradients across the uterus in women in labor and not in labor (Davidson et al). 1987;157:54-8
Fetal heart rate response to vibratory acoustic stimulation predicts fetal pH in labor (Edersheim et al). 1987;157:1557-60
In vitro conversion of pregnenolone to progesterone in human term placenta and fetal membranes before and after onset of labor (Khan-Dawood). 1987;157:1333-7
Influence of umbilical vein administration of oxytocin on the third stage of labor: a randomized, double-blind, placebo-controlled study (Chestnut and Wilcox). 1987;157:160-2
Neonatal seizures after cesarean delivery: higher risk with labor (Spellacy et al). 1987;157:377-9
The normal parturient's admission temperature (Acker et al). 1987;157:308-11
Obstetric outcome of patients with a previous episode of spurious labor (Arulkumaran et al). 1987;157:17-20
Previous cesarean delivery and trial of labor (Fribourg) (Letter); (Finley) (Reply). 1987;157:1014-5
Uterine and umbilical artery velocimetry during normal labor (Fleischer et al). 1987;157:40-3
When does a statistical fact become an ethical imperative? (Silver and Minogue). 1987;157:229-33 (Clin. opinion)

Labor, premature
Arachidonate lipoxygenase metabolites in amniotic fluid of women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1454-60
Effects of the antiprogesterone RU 486 on preterm birth in the rat (Garfield et al). 1987;157:1281-5
Increased boy-to-girl ratio in women with preterm labor beginning with contractions (Seki and Kato) (Letter). 1987;157:215-6
The presence or absence of fetal breathing movements as a predictor of outcome in preterm labor (Besinger et al). 1987;157:753-7
A prospective random trial of home uterine activity monitoring in pregnancies at increased risk of preterm labor (Iams et al). 1987;157:638-43
A prospective randomized study of the aggressive management of early labor (Cohen et al). 1987;157:1174-7
Risk scoring for preterm labor: Where do we go from here? (Main and Gabbe). 1987;157:789-93 (Clin. opinion)

Labor complications
Early third-trimester ultrasound screening in gestational diabetes to determine the risk of macrosomia and labor dystocia at term (Bochner et al). 1987;157:703-8
Infection and labor: the detection of endotoxin in amniotic fluid (Romero et al). 1987;157:815-9
Prostaglandin concentrations in amniotic fluid of women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1461-7

Lactate
Cord sampling for the evaluation of oxygenation and acid-base balance in human growth-retarded fetuses (Pardi et al). 1987;157:1221-8
The effect of mild hypoxemia maintained for twenty-four hours on maternal and fetal glucose, lactate, cortisol, and arginine vasopressin in pregnant sheep at 122 to 139 days' gestation (Towell et al). 1987;157:1550-7

Lactation; *see* **Breast-feeding**

Lactoferrin
Preliminary observations on lactoferrin secretion in human vaginal mucus: variation during the menstrual cycle, evidence of hormonal regulation, and implications for infection with *Neisseria gonorrhoeae* (Cohen et al). 1987;157:1122-5

Langerhans' cell
Langerhans' cells in the cervix (Hawthorn and MacLean) (Letter); (McArdle) (Reply). 1987;157:213-5

Laparoscopy
Carbon dioxide laser laparoscopy performed with a flexible fiber in humans (Baggish et al). 1987;157:1129-33

Unintended laparotomy associated with laparoscopic tubal sterilization (Franks et al). 1987;157:1102-5

Laparotomy
Unintended laparotomy associated with laparoscopic tubal sterilization (Franks et al). 1987;157:1102-5

Laser
Carbon dioxide laser laparoscopy performed with a flexible fiber in humans (Baggish et al). 1987;157:1129-33
Labial agglutination secondary to herpes simplex II infection (DeMarco et al). 1987;157:296-7
Laser excisional conization and laser vaporization for cervical intraepithelial neoplasia (Anderson) (Letter); (Baggish) (Reply). 1987;157:1322-3

Leukocyte
HLA antigen expression and induction by γ-interferon in cultured human trophoblasts (Feinman et al). 1987;157;1429-34
Human leukocyte antigen associated with endometrial carcinoma with a new classification of endometrial carcinoma based on its etiology (Kanuma and Igarashi). 1987;157:427-32
Leukocyte esterase activity in human amniotic fluid for the rapid detection of chorioamnionitis (Hoskins et al). 1987;157:730-2
Recurrent spontaneous abortion and human leukocyte antigen DRw8 (Takamizawa et al) (Letter). 1987;157: 514-5

Levonorgestrel
A new delivery system for contraceptive steroids (Segal). 1987;157:1090-2

Liley chart
Have Liley charts outlived their usefulness? (Duhring) (Letter); (Nicolaides) (Reply). 1987;157:1011-2

***Limulus* amebocyte**
Infection and labor: the detection of endotoxin in amniotic fluid (Romero et al). 1987;157:815-9

Lipids
Postprandial walking exercise in pregnant insulin-dependent (type 1) diabetic women: reduction of plasma lipid levels but absence of a significant effect on glycemic control (Hollingsworth and Moore). 1987;157: 1359-63

Lipoprotein
The binding and metabolism of low-density lipoprotein by skin fibroblasts of fetuses and newborns with anencephaly (Carr and Parker). 1987;157:1351-5
Metabolism of lipoproteins by human fetal hepatocytes (Carr). 1987;157:1338-44

β-Lipotropin
Proopiomelanocortin-related peptides and methionine enkephalin in human follicular fluid: changes during the menstrual cycle (Petraglia et al). 1987;157:142-6

Listeria
Fetal death: diagnosis and management (Pitkin). 1987;157:583-9

Low birth weight
Formulas for fetal weight estimation by ultrasound measurements based on neonatal specific gravities and volumes (Shinozuka et al). 1987;157:1140-5
Status of infants at birth and risk for adverse neonatal events and long-term sequelae: a study in low birth weight infants (Luthy et al). 1987;157:676-9

Low-density lipoprotein
The binding and metabolism of low-density lipoprotein by skin fibroblasts of fetuses and newborns with anencephaly (Carr and Parker). 1987;157:1351-5

Lung
Cholesteryl palmitate as a predictor of fetal lung maturity (Ludmir et al). 1987;157:84-8
Drug accumulation in lung fluid of the fetal lamb after maternal or fetal administration (Riggs et al). 1987;157:1286-91
Effects of norepinephrine on lung fluid flow rate in the chronically catheterized fetal lamb (Higuchi et al). 1987;157:986-90
Transplacental stimulation of functional and morphologic fetal rabbit lung maturation: effect of thyrotropin-releasing hormone (Devaskar et al). 1987;157:460-4

Lupus erythematosus
Fetal death: diagnosis and management (Pitkin). 1987;157:583-9
Second-trimester fetal monitoring and preterm delivery in pregnancies with systemic lupus erythematosus and/or circulating anticoagulant (Druzin et al). 1987;157:1503-10

Luteinizing hormone
Acute effects of exercise on plasma catecholamines in sedentary and athletic women with normal and abnormal menses (Chin et al). 1987;157:938-44

Lymphocyte
Lymphocyte-reactive antibodies and recurrent early pregnancy failure (Biddle et al) (Letter). 1987;157:785-6
Suppression of lymphocyte reactivity in vitro by supernatants of explants of human endometrium (Wang et al). 1987;157:956-63

M

Macrosomia
Early third-trimester ultrasound screening in gestational diabetes to determine the risk of macrosomia and labor dystocia at term (Bochner et al). 1987;157:703-8

Magnesium sulfate
Cerebrospinal fluid levels of magnesium in patients with preeclampsia after treatment with intravenous magnesium sulfate: a preliminary report (Thurnau et al). 1987;157:1435-8
The effect of oxytocin infusion on the pharmacokinetics of intramuscular magnesium sulfate therapy (Bloss et al). 1987;157:156-60
Magnesium and zinc status during the menstrual cycle (Deuster et al). 1987;157:964-8
Profound hypotension complicating magnesium therapy (Frohlich) (Letter). 1987;157:513

Magnetic resonance imaging
Abdominal pregnancy: magnetic resonance identification with ultrasonographic follow-up of placental involution (Spanta et al). 1987;157:887-9
Magnetic resonance imaging of monkey placenta with manganese enhancement (Kay et al). 1987;157:185-9

Male contraception
Experiences with gossypol as a male pill (Liu et al). 1987;157:1079-81

Malignancy; *see also* **Carcinoma; Neoplasia; Tumor**
Serum copper level in gynecologic malignancies (Margalioth et al). 1987;157:93-6

Mammography
Breast galactography in the treatment of infected cysts (Tihansky and DiBlasio). 1987;157:1278-80

Manganese
Magnetic resonance imaging of monkey placenta with manganese enhancement (Kay et al). 1987;157: 185-9

Maternal age
Pregnancy outcome in medically complicated and uncomplicated patients aged 40 years or older (Lehmann and Chism). 1987;157:738-42
Maternal ambulation
The effects of maternal ambulation on the nonstress test (Devoe et al). 1987;157:240-4
Maternal mortality
A thirty-year review of maternal mortality in Oklahoma, 1950 through 1979 (Moses et al). 1987;157:1189-94
Maternotrophoblastic border
Echocardiographic and anatomic studies of the maternotrophoblastic border during the first trimester of pregnancy (Hustin and Schaaps). 1987;157:162-8
Mean arterial pressure
Blood pressure in the midtrimester and future eclampsia (Chesley and Sibai). 1987;157:1258-61
Meclofenamate
Simultaneous objective and subjective evaluation of meclofenamate sodium in the treatment of primary dysmenorrhea (Smith and Powell). 1987;157:611-8
Treatment of menorrhagia with meclofenamate sodium (Vargyas et al). 1987;157:944-50
Meconium
Effects of alterations of zinc-to-phosphorus ratios and meconium content on Group B *Streptococcus* growth in human amniotic fluid in vitro (Hoskins et al). 1987;157:770-3
Membranes; *see* **Fetal membranes**
Menopause
Continuous estrogen/progestin therapy in menopause (Prough et al). 1987;157:1449-53
Follicle-stimulating hormone is the main determinant of follicular recruitment and development in ovulation induction with human menopausal gonadotropin (Vermesh and Kletzky). 1987;157:1397-402
Menstrual and reproductive factors and the risk of myocardial infarction in women under 55 years of age (La Vecchia et al). 1987;157:1108-12
Modulating actions of estradiol on gonadotropin-releasing hormone–stimulated prolactin secretion in postmenopausal individuals (Christiansen et al). 1987;157:320-5
Menorrhagia
Treatment of menorrhagia with meclofenamate sodium (Vargyas et al). 1987;157:944-50
Menstruation
Acute effects of exercise on plasma catecholamines in sedentary and athletic women with normal and abnormal menses (Chin et al). 1987;157:938-44
Influence of the menstrual cycle on glucose tolerance and insulin secretion (Bonora et al). 1987;157:140-1
Magnesium and zinc status during the menstrual cycle (Deuster et al). 1987;157:964-8
Menstrual and reproductive factors and the risk of myocardial infarction in women under fifty-five years of age (La Vecchia et al). 1987;157:1108-12
Preliminary observations on lactoferrin secretion in human vaginal mucus: variation during the menstrual cycle, evidence of hormonal regulation, and implications for infection with *Neisseria gonorrhoeae* (Cohen et al). 1987;157:1122-5
Proopiomelanocortin-related peptides and methionine enkephalin in human follicular fluid: changes during the menstrual cycle (Petraglia et al). 1987;157:142-6
Mesometrium
Characteristics of the electromyogram recorded from the mesometrium of the pregnant ewe from 106 days' gestation to delivery: similarities with and differences from the electromyogram obtained from the myometrium (Figueroa et al). 1987;157:991-8
Metabolism
The binding and metabolism of low-density lipoprotein by skin fibroblasts of fetuses and newborns with anencephaly (Carr and Parker). 1987;157:1351-5
Cerebral oxidative metabolism in fetal sheep with multiple-dose ethanol infusion (Richardson et al). 1987;157:1496-502
A hypothesis concerning the general basis of organogenetic congenital anomalies (Naftolin et al). 1987;157:1-4 (Clin. opinion)
Metabolism of lipoproteins by human fetal hepatocytes (Carr). 1987;157:1338-44
The significance of one abnormal glucose tolerance test value on adverse outcome in pregnancy (Langer et al). 1987;157:758-63
Steroid synthetic and prostaglandin metabolizing activity is present in different cell populations from human fetal membranes and decidua (Challis and Vaughan). 1987;157:1474-81
Metaplasia
Endometrial metaplasia associated with endometrial adenocarcinoma (Andersen et al). 1987;157:597-604
Methimazole
Antithyroid drugs: to breast-feed or not to breast-feed (Cooper). 1987;157:234-5 (Clin. opinion)
Methionine enkephalin
Proopiomelanocortin-related peptides and methionine enkephalin in human follicular fluid: changes during the menstrual cycle (Petraglia et al). 1987;157:142-6
Methotrexate
Treatment of nonmetastatic gestational trophoblastic disease with oral methotrexate (Barter et al). 1987;157:1166-8
Metoclopramide
Drug accumulation in lung fluid of the fetal lamb after maternal or fetal administration (Riggs et al). 1987;157:1286-91
Mexiletine
Mexiletine use in pregnancy and lactation (Lownes and Ives). 1987;157:446-7
Microadenoma
In vivo and in vitro modulation of growth hormone and prolactin of a mixed somatotropic-lactotropic pituitary microadenoma (Muechler et al). 1987;157:453-5
Microsomia
Possible vascular disruptive origin of hemifacial microsomia? (Schinzel) (Letter). 1987;157:1319
Microsurgery
Conservative surgical management of isthmic ectopic pregnancies (Smith et al). 1987;157:604-10
Monitoring; *see* **Fetal monitoring**
Monoamniotic twins
Antenatal diagnosis and management of monoamniotic twins (Rodis et al). 1987;157:1255-7
Monoclonal antibody
Diagnostic imaging of gynecologic tumors with the monoclonal antibody 791T/36 (Powell et al). 1987;157:28-34
Morality
Morality of induced abortion and freedom of choice (Fribourg) (Letter); (Hill) (Reply). 1987;157:215

Morbidity
Careful surgical technique can reduce infectious morbidity after cesarean section (Lyon and Richardson). 1987;157:557-62
Cocaine use during pregnancy: adverse perinatal outcome (MacGregor et al). 1987;157:686-90
Leukocyte esterase activity in human amniotic fluid for the rapid detection of chorioamnionitis (Hoskins et al). 1987;157:730-2
Prophylactic antibiotics for cesarean delivery: a simple cost-effective strategy for prevention of postoperative morbidity (Duff). 1987;157:794-8 (Clin. opinion)
Regional program for prevention of premature birth in northwestern North Carolina (Meis et al). 1987;157:550-6

Morphometrics
Neonatal morphometrics and perinatal outcome: Who is growth retarded? (Patterson and Pouliot). 1987;157:691-3

Mortality; *see also* **Death**
Evaluation of a perinatal grief support team (Lake et al). 1987;157:1203-6
Review of causes of perinatal mortality in a regional perinatal center, 1980 to 1984 (Ohlsson et al). 1987;157:443-5
A thirty-year review of maternal mortality in Oklahoma, 1950 through 1979 (Moses et al). 1987;157:1189-94

Mucus
Preliminary observations on lactoferrin secretion in human vaginal mucus: variation during the menstrual cycle, evidence of hormonal regulation, and implications for infection with *Neisseria gonorrhoeae* (Cohen et al). 1987;157:1122-5

Mycotic aneurysm
Mycotic aneurysms in pregnancy (Boike et al). 1987;157:340-1

Myocardial infarction
Coagulation effects of oral contraception (Bonnar). 1987;157:1042-8
Menstrual and reproductive factors and the risk of myocardial infarction in women under fifty-five years of age (La Vecchia et al). 1987;157:1108-12
Myocardial infarction in the puerperium (Feldman) (Letter); (Iffy et al) (Reply). 1987;157:515-6

Myometrium
Changes in cyclic adenosine monophosphate–phosphodiesterase activity in nonpregnant and pregnant human myometrium (Kofinas et al). 1987;157:733-8
Characteristics of the electromyogram recorded from the mesometrium of the pregnant ewe from 106 days' gestation to delivery: similarities with and differences from the electromyogram obtained from the myometrium (Figueroa et al). 1987;157:991-8
The effects of aminophylline and nifedipine on contractility of isolated pregnant human myometrium (Bird et al). 1987;157:171-7
Effects of the antiprogesterone RU 486 on preterm birth in the rat (Garfield et al). 1987;157:1281-5
Endometrial and myometrial effects of progesterone antagonists in pregnant guinea pigs (Elger et al). 1987;157:1065-74
A new look at uterine muscle contraction (Carsten and Miller). 1987;157:1303-15 (Curr. dev.)

Myosin
A new look at uterine muscle contraction (Carsten and Miller). 1987;157:1303-15 (Curr. dev.)

N

Natriuretic peptide
Plasma atrial natriuretic peptide response to volume expansion in the ovine fetus (Ross et al). 1987;157:1292-7

Natural family planning
Natural family planning (Brown et al). 1987;157:1082-9

Natural killer cells
Enhancement of maternal and neonatal natural killer cell activity with interleukin-2 (Baker et al). 1987;157:780-1

Necrotizing fasciitis
Necrotizing fasciitis of the vulva (Roberts). 1987;157:568-71

Needle puncture
Cervical endometriosis: facilitated diagnosis by fine needle aspiration cytologic testing (Veiga-Ferreira et al). 1987;157:849-56
In vitro training model for diagnostic and therapeutic fetal intravascular needle puncture (Timor-Tritsch and Yeh). 1987;157:858-9

Negroid race
Maternal serum α-fetoprotein screening. III. Pitfalls in evaluating black gravid women (Macri et al). 1987;157:820-2

Neisseria gonorrhoeae
Preliminary observations on lactoferrin secretion in human vaginal mucus: variation during the menstrual cycle, evidence of hormonal regulation, and implications for infection with *Neisseria gonorrhoeae* (Cohen et al). 1987;157:1122-5

Neonate
Abnormalities in platelet antiglobulin tests in preeclamptic mothers and their neonates (Samuels et al). 1987;157:109-13
The binding and metabolism of low-density lipoprotein by skin fibroblasts of fetuses and newborns with anencephaly (Carr and Parker) 1987;157:1351-5
Circulating neurohypophyseal hormones in anencephalic infants (Oosterbaan and Swaab). 1987;157:117-9
Formulas for fetal weight estimation by ultrasound measurements based on neonatal specific gravities and volumes (Shinozuka et al). 1987;157:1140-5
Growth hormone, somatomedin C, and nonsuppressible insulin-like activity levels compared in premature, small, average birth weight, and large infants (Samaan et al). 1987;157:1524-8
Neonatal auditory acuity following in utero vibratory acoustic stimulation (Ohel et al). 1987;157:440-1
Neonatal morphometrics and perinatal outcome: Who is growth retarded? (Patterson and Pouliot). 1987;157:691-3
Neonatal seizures after cesarean delivery: higher risk with labor (Spellacy et al). 1987;157:377-9
Reduction of group B streptococcal maternal and neonatal infections in preterm pregnancies with premature rupture of membranes through a rapid identification test (Morales and Lim). 1987;157:13-6
Review of causes of perinatal mortality in a regional perinatal center, 1980 to 1984 (Ohlsson et al). 1987;157:443-5

Neoplasia; *see also* **Carcinoma; Malignancy; Tumor**
Colposcopic correlates of cervical papillomavirus infection (Follen et al). 1987;157:809-14

Evaluation of the atypical Pap smear (Jones et al). 1987;157:544-9
Laser excisional conization and laser vaporization for cervical intraepithelial neoplasia (Anderson) (Letter); (Baggish) (Reply). 1987;157:1322-3
Multiple primary gynecologic neoplasms (Rose et al). 1987;157:261-7
The results of cryosurgical treatment of cervical intraepithelial neoplasia at one, five, and ten years (Benedet et al). 1987;157:268-73

Nerve entrapment
Nerve entrapment after Pfannenstiel incision (Sippo et al). 1987;157:420-1

Neurofibromatosis
Fetal growth retardation as a complication of pregnancy in patients with neurofibromatosis (Blickstein and Lancet). 1987;157:343

Neurohypophyseal hormones
Circulating neurohypophyseal hormones in anencephalic infants (Oosterbaan and Swaab). 1987;157:117-9

Neuromuscular blockade
The use of fetal neuromuscular blockade during intrauterine procedures (Moise et al). 1987;157:874-9

Neutrophil
Host defense during pregnancy: neutrophil chemotaxis and adherence (Krause et al). 1987;157:274-80

Newborn; *see* **Neonate**

Nicardipine
Effects of calcium entry blocker (nicardipine) tocolysis in rhesus macaques: fetal plasma concentrations and cardiorespiratory changes (Ducsay et al). 1987;157:1482-6

Nifedipine
The effects of aminophylline and nifedipine on contractility of isolated pregnant human myometrium (Bird et al). 1987;157:171-7
Nifedipine: effects on fetal and maternal hemodynamics in pregnant sheep (Harake et al). 1987;157:1003-8

Nipple stimulation
Breast stimulation test and oxytocin challenge test in fetal surveillance: a prospective randomized study (Lipitz et al). 1987;157:1178-81
A prospective comparative study of the extended nonstress test and the nipple stimulation contraction stress test (Devoe et al). 1987;157:531-7
A prospective evaluation of nipple stimulation techniques for contraction stress testing (Keegan et al). 1987;157:121-5

Noise
Local cerebral glucose utilization in fetal sheep exposed to noise (Abrams et al). 1987;157:456-60

Nonstress test
Antepartum predictors of fetal distress in postterm pregnancy (Bochner et al). 1987;157:353-8
Criteria for interpretation of a reactive nonstress test (Willis) (Letter); (Erskine et al) (Reply). 1987;157:213
The effects of maternal ambulation on the nonstress test (Devoe et al). 1987;157:240-4
Patterns of human fetal heart rate accelerations from 26 weeks to term (Gagnon et al). 1987;157:743-8
A prospective comparative study of the extended nonstress test and the nipple stimulation contraction stress test (Devoe et al). 1987;157:531-7

Norepinephrine
Effects of norepinephrine on lung fluid flow rate in the chronically catheterized fetal lamb (Higuchi et al). 1987;157:986-90

Norgestimate
New progestogens in oral contraceptives (Runnebaum and Rabe). 1987;157:1059-63

Nuchal fold
Soft tissue nuchal fold in the second-trimester fetus: standards for normal measurements compared with those in Down syndrome (Benacerraf and Frigoletto). 1987;157:1146-9

O

Obstetric residents
Pregnancy among obstetricians: a comparison of births before, during, and after residency (Grunebaum et al). 1987;157:79-83

Obstruction
Mechanical intestinal obstruction in patients with gynecologic disease: a review of 368 patients (Krebs and Goplerud). 1987;157:577-83

Oligohydramnios
Acute oligohydramnios in postdate pregnancy (Clement et al). 1987;157:884-6
Elevated maternal serum α-fetoprotein levels and oligohydramnios: poor prognosis for pregnancy outcome (Dyer et al). 1987;157:336-9
Ultrasonic ratio of fetal thoracic to abdominal circumference: an association with fetal pulmonary hypoplasia (Johnson et al). 1987;157:764-9

Oocyte
Transurethral ultrasound-guided oocyte retrieval for in vitro fertilization (Padilla et al). 1987;157:622-6

Oral contraception
Coagulation effects of oral contraception (Bonnar). 1987;157:1042-8
Contraception: an overview (Hammerstein). 1987;157:1020-3
Hormonal contraception: benefits versus risks (Goldzieher). 1987;157:1023-8
International symposium on contraception. Part 1: oral contraception. 1987;157:1019-63
International symposium on contraception. Part 1: oral contraception: introduction (Speroff). 1987;157:1019
Menstrual and reproductive factors and the risk of myocardial infarction in women under 55 years of age (La Vecchia et al). 1987;157:1108-12
Metabolic effects of oral contraceptives (Gaspard). 1987;157:1029-41
New progestogens in oral contraceptives (Runnebaum and Rabe). 1987;157:1059-63
Phasic approach to oral contraceptives (Hale). 1987;157:1052-8
Progestogen potency in oral contraceptive pills (Gillmer). 1987;157:1048-52
Venous thrombosis in patients with cardiac pacemakers and oral contraceptive use (Rao) (Letter). 1987;157:516-7

Organogenesis
Absence of clomiphene and/or active metabolites in blood of clomiphene citrate–treated patients during organogenesis: determination by radioreceptor assay (Geier et al) (Letter). 1987;157:1009
A hypothesis concerning the general basis of organogenetic congenital anomalies (Naftolin et al). 1987;157:1-4 (Clin. opinion)

Osmotic pressure
Mechanisms for reduced colloid osmotic pressure in preeclampsia (Bhatia et al). 1987;157:106-8

Outcome of pregnancy
Cocaine use during pregnancy: adverse perinatal outcome (MacGregor et al). 1987;157:686-90
Fetal death: diagnosis and management (Pitkin). 1987;157:583-9
Hysterosalpingographic evaluation of tubal patency after ectopic pregnancy (Mitchell et al). 1987;157:618-22
Neonatal morphometrics and perinatal outcome: who is growth retarded? (Patterson and Pouliot). 1987;157:691-3
Pregnancy outcome in medically complicated and uncomplicated patients aged 40 years or older (Lehmann and Chism). 1987;157:738-42
The presence or absence of fetal breathing movements as a predictor of outcome in preterm labor (Besinger et al). 1987;157:753-7
Recurrent small for gestational age birth: perinatal risks and outcome (Wolfe et al). 1987;157:288-93
Responsibility, obligation, and duty (Dunn). 1987;157:521-30
The significance of one abnormal glucose tolerance test value on adverse outcome in pregnancy (Langer et al). 1987;157:758-63

Ovarian carcinoma
Another look at the second-assessment procedure for ovarian epithelial carcinoma (Gallup et al). 1987;157:590-6
Cigarette smoking and the risk of female reproductive cancer (Stockwell and Lyman). 1987;157:35-40
Evaluation of serum CA 125 levels in the monitoring of ovarian cancer (Vergote et al). 1987;157:88-92

Ovarian cyst
Theca-lutein ovarian cysts associated with homozygous α-thalassemia (Miller et al). 1987;157:912-4

Ovary
Human ovarian oxytocin and steroid hormones (Auletta and Flint) (Letter); (Khan-Dawood and Dawood) (Reply). 1987;157:1010-1
Insulin resistance and abnormal ovarian responses to human chorionic gonadotropin in chronically anovulatory women (Kustin et al). 1987;157:1468-73
Ovarian prostaglandin synthase: immunohistochemical localization in the rat (Curry et al). 1987;157:537-43

Ovulation
The effects of proteolytic enzymes on in vitro ovulation in the rabbit (Yoshimura et al). 1987;157:468-75
Evidence that estrogen may be a key factor in hyperprolactinemic anovulation: a case report (Sakamoto et al). 1987;157:318-9
Follicle-stimulating hormone is the main determinant of follicular recruitment and development in ovulation induction with human menopausal gonadotropin (Vermesh and Kletzky). 1987;157:1397-402
Insulin resistance and abnormal ovarian responses to human chorionic gonadotropin in chronically anovulatory women (Kustin et al). 1987;157:1468-73
Ovarian prostaglandin synthase: immunohistochemical localization in the rat (Curry et al). 1987;157:537-43
Sonographic evaluation of the cervix during ovulation induction (Hill et al). 1987;157:1170-4

Oxygenation
Cord sampling for the evaluation of oxygenation and acid-base balance in human growth-retarded fetuses (Pardi et al). 1987;157:1221-8

Oxytocin
Breast stimulation test and oxytocin challenge test in fetal surveillance: a prospective randomized study (Lipitz et al). 1987;157:1178-81
Circulating neurohypophyseal hormones in anencephalic infants (Oosterbaan and Swaab). 1987;157:117-9
The effect of oxytocin infusion on the pharmacokinetics of intramuscular magnesium sulfate therapy (Bloss et al). 1987;157:156-60
Evaluation of 1-deamino-[D-Tyr(Oethyl)^2,Thr^4,Orn^8] vasotocin, an oxytocin antagonist, in animal models of uterine contractility and preterm labor: a new tocolytic agent (Hahn et al). 1987;157:977-82
Human ovarian oxytocin and steroid hormones (Auletta and Flint) (Letter); (Khan-Dawood and Dawood) (Reply). 1987;157:1010-1
Influence of umbilical vein administration of oxytocin on the third stage of labor: a randomized, double-blind, placebo-controlled study (Chestnut and Wilcox). 1987;157:160-2
A new look at uterine muscle contraction (Carsten and Miller). 1987;157:1303-15 (Curr. dev.)

P

Pacemaker
Ultrasound evaluation of tachycardia-induced hydrops in the fetal lamb (Nimrod et al). 1987;157:655-9
Venous thrombosis in patients with cardiac pacemakers and oral contraceptive use (Rao) (Letter). 1987;157:516-7

Palsy
Erb's palsy and fetal bruising after external cephalic version: case report (Petrikovsky et al). 1987;157:258

Pancuronium
The use of fetal neuromuscular blockade during intrauterine procedures (Moise et al). 1987;157:874-9

Papanicolaou smear
Colposcopic evaluation of abnormal Papanicolaou smears in pregnancy (Benedet et al). 1987;157:932-7
Detection of *Chlamydia trachomatis* cervical infection: a comparison of Papanicolaou and immunofluorescent staining with cell culture (Quinn et al). 1987;157:394-9
Evaluation of the atypical Pap smear (Jones et al). 1987;157:544-9
A reusable plastic training model for teaching Papanicolaou smear technique (Beckmann et al). 1987;157:259-60

Papers
Papers of the Society for Gynecologic Investigation. 1987;157:1333-560

Papillomavirus
Colposcopic correlates of cervical papillomavirus infection (Follen et al). 1987;157:809-14

Paralysis
Erb's palsy and fetal bruising after external cephalic version: case report (Petrikovsky et al). 1987;157:258
The use of fetal neuromuscular blockade during intrauterine procedures (Moise et al). 1987;157:874-9

Parturition; *see also* **Delivery; Labor**
Decreased elastic fibers and desmosine content in incompetent cervix (Leppert et al). 1987;157:1134-9
The normal parturient's admission temperature (Acker et al). 1987;157:308-11

Pelvic adhesion
Prevention of pelvic adhesion formation by different modalities of treatment (Fayez and Schneider). 1987;157:1184-8

Pelvic infection; *see also* **Infection**
Contraceptive use, pelvic inflammatory disease, and fertility

problems among American women: 1982 (Aral et al). 1987;157:59-64
Single-agent therapy for women with acute polymicrobial pelvic infections (Hemsell et al). 1987;157:488-90
Treatment and prevention of female pelvic infection: the quest for single-agent therapy (Cunningham). 1987;157:485-8

Pemphigus
Pemphigus in pregnancy: a reevaluation of fetal risk (Metzker and Merlob) (Letter). 1987;157:1012-3

Peptides
Proopiomelanocortin-related peptides and methionine enkephalin in human follicular fluid: changes during the menstrual cycle (Petraglia et al). 1987;157:142-6

Periareolar sinus
Breast galactography in the treatment of infected cysts (Tihansky and DiBlasio). 1987;157:1278-80

Perinatal asphyxia
Indicators of perinatal asphyxia (Hollander et al). 1987;157:839-42
Review of causes of perinatal mortality in a regional perinatal center, 1980 to 1984 (Ohlsson et al). 1987;157:443-5

Perinatal morbidity; *see* **Morbidity**

Perinatal mortality; *see* **Mortality**

Perinatal outcome; *see* **Outcome of pregnancy**

Perinatal risk; *see* **Outcome of pregnancy**

Perineal infiltration
2-Chloroprocaine for local perineal infiltration (Philipson et al). 1987;157:1275-8

Peritoneal abnormalities
Local peritoneal factors: their role in infertility associated with endometriosis (Awadalla et al). 1987;157:1207-14

Pfannenstiel incision
Nerve entrapment after Pfannenstiel incision (Sippo et al). 1987;157:420-1

pH
Fetal heart rate response to vibratory acoustic stimulation predicts fetal pH in labor (Edersheim et al). 1987;157:1557-60
The relationships among the fetal biophysical profile, umbilical cord pH, and Apgar scores (Vintzileos et al). 1987;157:627-31
Scalp heat flux and its relationship to scalp blood pH of the fetus (Rudelstorfer et al). 1987;157:372-7
Status of infants at birth and risk for adverse neonatal events and long-term sequelae: a study in low birth weight infants (Luthy et al). 1987;157:676-9
Umbilical cord blood pH and Apgar score as an index of neonatal health (Josten et al). 1987;157:843-8

Pharmacokinetics
The effect of oxytocin infusion on the pharmacokinetics of intramuscular magnesium sulfate therapy (Bloss et al). 1987;157:156-60

Phosphatidylglycerol
The reliability and clinical use of a rapid phosphatidylglycerol assay in normal and diabetic pregnancies (Saad et al). 1987;157:1516-20

Phosphodiesterase
Changes in cyclic adenosine monophosphate–phosphodiesterase activity in nonpregnant and pregnant human myometrium (Kofinas et al). 1987;157:733-8

Phosphorus
Effects of alterations of zinc-to-phosphorus ratios and meconium content on group B *Streptococcus* growth in human amniotic fluid in vitro (Hoskins et al). 1987;157:770-3
A new look at uterine muscle contraction (Carsten and Miller). 1987;157:1303-15 (Curr. dev.)

Piperacillin
Single-dose versus multiple-dose piperacillin prophylaxis in primary cesarean operation (Gall and Hill). 1987;157:502-6

Pituitary gland
In vivo and in vitro modulation of growth hormone and prolactin of a mixed somatotropic-lactotropic pituitary microadenoma (Muechler et al). 1987;157:453-5
Pituitary responses to synthetic corticotropin-releasing hormone: absence of modulatory effects by estrogen and progestin (Liu et al). 1987;157:1387-91

Placenta
Abdominal pregnancy: magnetic resonance identification with ultrasonographic follow-up of placental involution (Spanta et al). 1987;157:887-9
2-Chloroprocaine for local perineal infiltration (Philipson et al). 1987;157:1275-8
Cyclooxygenase inhibition reduces placental transfer: reversal by carbacyclin (Kuhn and Stuart). 1987;157:194-8
Drug accumulation in lung fluid of the fetal lamb after maternal or fetal administration (Riggs et al). 1987;157:1286-91
The effect of smoking on placental and fetal zinc status (Kuhnert et al). 1987;157:1241-6
Hypoxia-induced fetoplacental vasoconstriction in perfused human placental cotyledons (Howard et al). 1987;157:1261-6
In vitro conversion of pregnenolone to progesterone in human term placenta and fetal membranes before and after onset of labor (Khan-Dawood). 1987;157:1333-7
Increased fetoplacental active renin production in pregnancy-induced hypertension (Brar et al). 1987;157:363-7
Influence of umbilical vein administration of oxytocin on the third stage of labor: a randomized, double-blind, placebo-controlled study (Chestnut and Wilcox). 1987;157:160-2
Insufficient transplacental digoxin transfer in severe hydrops fetalis (Younis and Granat). 1987;157:1268-9
Isolation of acquired immunodeficiency syndrome virus from the placenta (Hill et al). 1987;157:10-1
Magnetic resonance imaging of monkey placenta with manganese enhancement (Kay et al). 1987;157:185-9
Placental bed biopsy technique and vascular lesions (Labarrere) (Letter); (Robertson) (Reply). 1987;157:1320-2
Placental glycolysis and energy metabolism in preeclampsia (Bloxam et al). 1987;157:97-101
Prevention of recurrent idiopathic fetal growth retardation by low-dose aspirin and dipyridamole (Wallenburg and Rotmans). 1987;157:1230-5
Transplacental stimulation of functional and morphologic fetal rabbit lung maturation: effect of thyrotropin-releasing hormone (Devaskar et al). 1987;157:460-4
Umbilical artery flow velocity waveforms and placental resistance: the effects of embolization of the umbilical circulation (Trudinger et al). 1987;157:1443-8
Umbilical artery flow velocity waveforms and the placental vascular bed (McCowan et al). 1987;157:900-2
The umbilical cord twist: origin, direction, and relevance (Lacro et al). 1987;157:833-8

Placenta percreta
Acute abdomen caused by placenta percreta in the second trimester (Archer and Furlong). 1987;157:146-7

Plasma
Acute effects of exercise on plasma catecholamines in sedentary and athletic women with normal and abnormal menses (Chin et al). 1987;157:938-44
β-Adrenergic receptor agonist infusion increases plasma prostaglandin F levels in pregnant sheep (Casper and Lye). 1987;157:998-1003
Inhibitory effect of quinidine on plasma pseudocholinesterase activity in pregnant women (Kambam et al). 1987;157:897-9
Effects of calcium entry blocker (nicardipine) tocolysis in rhesus macaques: fetal plasma concentrations and cardiorespiratory changes (Ducsay et al). 1987;157:1482-6
Mechanisms for reduced colloid osmotic pressure in preeclampsia (Bhatia et al). 1987;157:106-8
Plasma atrial natriuretic peptide response to volume expansion in the ovine fetus (Ross et al). 1987;157:1292-7
Postprandial walking exercise in pregnant insulin-dependent (type 1) diabetic women: reduction of plasma lipid levels but absence of a significant effect on glycemic control (Hollingsworth and Moore). 1987;157:1359-63
Seminal plasma proteins of fertile and infertile men analyzed by two-dimensional electrophoresis (Ayyagari et al). 1987;157:1528-33

Platelets
Abnormalities in platelet antiglobulin tests in preeclamptic mothers and their neonates (Samuels et al). 1987;157:109-13
Increased thromboxane biosynthesis in normal pregnancy is mainly derived from platelets (Fitzgerald et al). 1987;157:325-30
Prevention of recurrent idiopathic fetal growth retardation by low-dose aspirin and dipyridamole (Wallenburg and Rotmans). 1987;157:1230-5
Validity of intrapartum diagnosis of fetal thrombocytopenia (Christiaens and Helmerhorst). 1987;157:864-5

Pleural effusion
Pleural effusions and pulmonary hypoplasia (Castillo et al). 1987;157:1252-5

Polycystic ovary syndrome
Human chorionic gonadotropin, estriol, and testosterone changes in two pregnancies with hyperreactio luteinalis (Muechler et al). 1987;157:1126-8

Polyhydramnios
Treatment of polyhydramnios with prostaglandin synthetase inhibitor (indomethacin) (Cabrol et al). 1987;157:422-6

Polyps
Sonographic diagnosis of a bladder polyp (Jensen and Lynne). 1987;157:1168-9

Ponderal index
In utero ponderal index as a prognostic factor in the evaluation of intrauterine growth retardation (Yagel et al). 1987;157:415-9

Postdate pregnancy
Acute oligohydramnios in postdate pregnancy (Clement et al). 1987;157:884-6
Antepartum predictors of fetal distress in postterm pregnancy (Bochner et al). 1987;157:353-8
Fetal umbilical artery flow velocimetry in postdate pregnancies (Guidetti et al). 1987;157:1521-3
Umbilical cord size and amniotic fluid volume in prolonged pregnancy (Silver et al). 1987;157:716-20

Postoperative morbidity
Prevention of pelvic adhesion formation by different modalities of treatment (Fayez and Schneider). 1987;157:1184-8
Prophylactic antibiotics for cesarean delivery: a simple cost-effective strategy for prevention of postoperative morbidity (Duff). 1987;157:794-8 (Clin. opinion)

Preeclampsia
Abnormalities in platelet antiglobulin tests in preeclamptic mothers and their neonates (Samuels et al). 1987;157:109-13
Acute atherosis in preeclampsia: maternal determinants and fetal outcome in the presence of the lesion (Khong et al). 1987;157:360-3
Calculated capillary hydrostatic pressure in normal pregnancy and preeclampsia (Øian and Maltau). 1987;157:102-6
Cerebrospinal fluid levels of magnesium in patients with preeclampsia after treatment with intravenous magnesium sulfate: a preliminary report (Thurnau et al). 1987;157:1435-8
Digoxin-like immunoreactive substance in pregnancy (Gonzalez et al). 1987;157:660-4
The effect of oxytocin infusion on the pharmacokinetics of intramuscular magnesium sulfate therapy (Bloss et al). 1987;157:156-60
Hereditary protein C deficiency during pregnancy (Brenner et al). 1987;157:1160-1
Increased tubular enzyme excretion in preeclampsia (Goren et al). 1987;157:906-8
Mechanisms for reduced colloid osmotic pressure in preeclampsia (Bhatia et al). 1987;157:106-8
Placental glycolysis and energy metabolism in preeclampsia (Bloxam et al). 1987;157:97-101
Preeclampsia, delivery, and the hemostatic system (Saleh et al). 1987;157:331-6

Pregnancy; *see also* **Pregnancy complications**
β-Adrenergic receptor agonist infusion increases plasma prostaglandin F levels in pregnant sheep (Casper and Lye). 1987;157:998-1003
Amniotic fluid α-fetoprotein levels and pregnancy outcome (Brumfield et al). 1987;157:822-5
Anorexia nervosa, bulimia, and pregnancy (Stewart et al). 1987;157:1194-8
The "breakfast tolerance test": screening for gestational diabetes with a standardized mixed nutrient meal (Coustan et al). 1987;157:1113-7
Caffeine-cigarette interaction on fetal growth (Beaulac-Baillargeon and Desrosiers). 1987;157:1236-40
Calculated capillary hydrostatic pressure in normal pregnancy and preeclampsia (Øian and Maltau). 1987;157:102-6
The cause of uterine softening in pregnancy (Jakobovits et al) (Letter). 1987;157:1013
Changes in cyclic adenosine monophosphate–phosphodiesterase activity in nonpregnant and pregnant human myometrium (Kofinas et al). 1987;157:733-8
Characteristics of the electromyogram recorded from the mesometrium of the pregnant ewe from 106 days' gestation to delivery: similarities with and differences from the electromyogram obtained from the myometrium (Figueroa et al). 1987;157:991-8
Cord serum bromide concentration: variation and lack of association with pregnancy outcome (Miller et al). 1987;157:826-30
Digoxin-like immunoreactive substance in pregnancy (Gonzalez et al). 1987;157:660-4

Disposition of acute, multiple-dose ethanol in the near-term pregnant ewe (Brien et al). 1987;157:204-11
Echocardiographic and anatomic studies of the maternotrophoblastic border during the first trimester of pregnancy (Hustin and Schaaps). 1987;157:162-8
The effect of mild hypoxemia maintained for twenty-four hours on maternal and fetal glucose, lactate, cortisol, and arginine vasopressin in pregnant sheep at 122 to 139 days' gestation (Towell et al). 1987;157:1550-7
Effect of pregnancy on surgically induced endometriosis in cynomolgus monkeys (Schenken et al). 1987;157:1392-6
Effects of aerobic and strength conditioning on pregnancy outcomes (Hall and Kaufmann). 1987;157:1199-203
The effects of aminophylline and nifedipine on contractility of isolated pregnant human myometrium (Bird et al). 1987;157:171-7
Effects of the antiprogesterone RU 486 on preterm birth in the rat (Garfield et al). 1987;157:1281-5
Effects of maternal glucose infusion on fetal acid-base status in human pregnancy (Philipson et al). 1987;157:866-73
Emotional responses of pregnant women to chorionic villi sampling or amniocentesis (Spencer and Cox). 1987;157:1155-60
Endometrial and myometrial effects of progesterone antagonists in pregnant guinea pigs (Elger et al). 1987;157:1065-74
Fetal assessment based on fetal biophysical profile scoring: experience in 19,221 referred high-risk pregnancies. II. An analysis of false-negative fetal deaths (Manning et al). 1987;157:880-4
Formulas for fetal weight estimation by ultrasound measurements based on neonatal specific gravities and volumes (Shinozuka et al). 1987;157:1140-5
Host defense during pregnancy: neutrophil chemotaxis and adherence (Krause et al). 1987;157:274-80
Increased thromboxane biosynthesis in normal pregnancy is mainly derived from platelets (Fitzgerald et al). 1987;157:325-30
Inhibitory effect of quinidine on plasma pseudocholinesterase activity in pregnant women (Kambam et al). 1987;157:897-9
Management of the diethylstilbestrol-exposed pregnant patient: a prospective study (Ludmir et al). 1987;157:665-9
Mexiletine use in pregnancy and lactation (Lownes and Ives). 1987;157:446-7
Nifedipine: effects on fetal and maternal hemodynamics in pregnant sheep (Harake et al). 1987;157:1003-8
Observations on the log human chorionic gonadotropin–time relationship in early pregnancy and its practical implications (Kadar and Romero). 1987;157:73-8
Pregnancy among obstetricians: a comparison of births before, during, and after residency (Grunebaum et al). 1987;157:79-83
A pregnant woman with a high level of naturally occurring immunoglobulin M antibodies to *Toxoplasma gondii* (Konishi). 1987;157:832-3
Prescription drug use before and during pregnancy in a Medicaid population (Piper et al). 1987;157:148-56
The prevalence of autoantibodies in pregnant and nonpregnant women (Patton et al). 1987;157:1345-50
The reliability and clinical use of a rapid phosphatidylglycerol assay in normal and diabetic pregnancies (Saad et al). 1987;157:1516-20
Riboflavin concentration in maternal and cord blood in human pregnancy (Kirshenbaum et al). 1987;157:748-52
Updated pregnancy rates for the Today contraceptive sponge (Edelman and North). 1987;157:1164-5
Varicella zoster antibody testing in the care of pregnant women exposed to varicella (McGregor et al). 1987;157:281-4

Pregnancy in adolescence
Teen pregnancies (Roush) (Letter); (Hollingsworth) (Reply). 1987;157:1011

Pregnancy, ectopic; *see* **Ectopic pregnancy**

Pregnancy, multiple
Antenatal diagnosis and management of monoamniotic twins (Rodis et al). 1987;157:1255-7
The length of the human umbilical cord in twin pregnancies (Soernes and Bakke). 1987;157:1229-30
Umbilical cord waveforms in fetal surveillance of twins (Saldana et al). 1987;157:712-5

Pregnancy, prolonged; *see* **Postdate pregnancy**

Pregnancy complications; *see also* **Pregnancy**
Anorexia nervosa, bulimia, and pregnancy (Stewart et al). 1987;157:1194-8
Arachidonate lipoxygenase metabolites in amniotic fluid of women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1454-60
Beneficial effects of U-63,557A, a thromboxane synthetase inhibitor, in an ovine model of pregnancy-induced hypertension (Keith et al). 1987;157:199-203
Blood pressure in the midtrimester and future eclampsia (Chesley and Sibai). 1987;157:1258-61
A classification of hypertension in pregnancy based on Doppler velocimetry (Ducey et al). 1987;157:680-5
Calculated capillary hydrostatic pressure in normal pregnancy and preeclampsia (Øian and Maltau). 1987;157:102-6
Cerebrospinal fluid levels of magnesium in patients with preeclampsia after treatment with intravenous magnesium sulfate: a preliminary report (Thurnau et al). 1987;157:1435-8
Colposcopic evaluation of abnormal Papanicolaou smears in pregnancy (Benedet et al). 1987;157:932-7
Disruption of embryonic and fetal development due to preimplantation chemical insults: a critical review (Iannaccone et al). 1987;157:476-84 (Curr. dev.)
Drug prescribing for thromboembolic disease during pregnancy (Greenspoon and Montoro) (Letter). 1987;157:784-5
Elevated maternal serum α-fetoprotein levels and oligohydramnios: poor prognosis for pregnancy outcome (Dyer et al). 1987;157:336-9
Factor XI deficiency presenting as hemarthrosis during pregnancy (Musclow et al). 1987;157:178-9
Fetal growth retardation as a complication of pregnancy in patients with neurofibromatosis (Blickstein and Lancet). 1987;157:343
First-trimester vaginal bleeding and the loss of chromosomally normal and abnormal conceptions (Strobino and Pantel-Silverman). 1987;157:1150-4
Gestational diabetes: insulin requirements in pregnancy (Langer et al). 1987;157:669-75
Gestational diabetes: maternal response to diet and insulin therapy as reflected by glycosylated hemoglobin concentration (Grandis et al). 1987;157:1118-21
Haptoglobin helps diagnose the HELLP syndrome (Poldre). 1987;157:1267
Hereditary protein C deficiency during pregnancy (Brenner et al). 1987;157:1160-1

Human chorionic gonadotropin, estriol, and testosterone changes in two pregnancies with hyperreactio luteinalis (Muechler et al). 1987;157:1126-8
Hyperimmunoglobulinemia E and pregnancy: a case report (Lindenbaum et al). 1987;157:1273-4
Hypertensive diseases of pregnancy: nulliparity, primiparity, multiparity, and gravidity (Reamy) (Letter); (Gleicher) (Reply). 1987;157:1012
Increased fetoplacental active renin production in pregnancy-induced hypertension (Brar et al). 1987;157:363-7
Lymphocyte-reactive antibodies and recurrent early pregnancy failure (Biddle et al) (Letter). 1987;157:785-6
Mycotic aneurysms in pregnancy (Boike et al). 1987;157:340-1
The origin of increased serum iron in pregnancy-induced hypertension (Samuels et al). 1987;157:721-5
Pemphigus in pregnancy: a reevaluation of fetal risk (Metzker and Merlob) (Letter). 1987;157:1012-3
Postprandial walking exercise in pregnant insulin-dependent (type 1) diabetic women: reduction of plasma lipid levels but absence of a significant effect on glycemic control (Hollingsworth and Moore). 1987;157:1359-63
Pregnancy in Henoch-Schönlein purpura (Joseph et al). 1987;157:911-2
The pregnant brain dead and the fetus: Must we always try to wrest life from death? (Loewy). 1987;157:1097-101 (Clin. opinion)
A prospective random trial of home uterine activity monitoring in pregnancies at increased risk of preterm labor (Iams et al). 1987;157:638-43
Prostaglandin concentrations in amniotic fluid of women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1461-7
Red blood cell zinc protoporphyrin testing for iron-deficiency anemia in pregnancy (Schifman et al). 1987;157:304-7
Reduction of group B streptococcal maternal and neonatal infections in preterm pregnancies with premature rupture of membranes through a rapid identification test (Morales and Lim). 1987;157:13-6
The reliability and clinical use of a rapid phosphatidylglycerol assay in normal and diabetic pregnancies (Saad et al). 1987;157:1516-20
Renal arterial blood flow velocity waveforms in pregnant women (Hata et al). 1987;157:1269-71
Restriction fragment length polymorphisms of the insulin gene hypervariable region in gestational onset diabetes mellitus (Ober et al). 1987;157:1364-8
A screening test (GBS-Test) for urogenital carriage of group B streptococci (Christensen and Christensen). 1987;157:341-2
Second-trimester fetal monitoring and preterm delivery in pregnancies with systemic lupus erythematosus and/or circulating anticoagulant (Druzin et al). 1987;157:1503-10
Soft tissue nuchal fold in the second-trimester fetus: standards for normal measurements compared with those in Down syndrome (Benacerraf and Frigoletto). 1987;157:1146-9
A thirty-year review of maternal mortality in Oklahoma, 1950 through 1979 (Moses et al). 1987;157:1189-94
The use of fetal biophysical profile improves pregnancy outcome in premature rupture of the membranes (Vintzileos et al). 1987;157:236-40

Pregnancy outcome; *see* **Outcome of pregnancy**

Pregnanediol
Natural family planning (Brown et al). 1987;157:1082-9

Pregnenolone
In vitro conversion of pregnenolone to progesterone in human term placenta and fetal membranes before and after onset of labor (Khan-Dawood). 1987;157:1333-7

Premature rupture of membranes; *see* **Fetal membranes**

Prematurity; *see also* **Preterm labor and delivery**
Genetic heterogeneity of prematurity and intrauterine growth retardation: clues from the Old Order Amish (Khoury and Cohen). 1987;157:400-10
Growth hormone, somatomedin C, and nonsuppressible insulin-like activity levels compared in premature, small, average birth weight, and large infants (Samaan et al). 1987;157:1524-8
Regional program for prevention of premature birth in northwestern North Carolina (Meis et al). 1987;157:550-6

Prenatal care
Barriers to receiving adequate prenatal care (Poland et al). 1987;157:297-303
Prescription drug use before and during pregnancy in a Medicaid population (Piper et al). 1987;157:148-56

Prenatal diagnosis; *see also* **Screening**
Fetal cerebellar growth unaffected by intrauterine growth retardation: a new parameter for prenatal diagnosis (Reece et al). 1987;157:632-8
Soft tissue nuchal fold in the second-trimester fetus: standards for normal measurements compared with those in Down syndrome (Benacerraf and Frigoletto). 1987;157:1146-9

Preterm labor and delivery
Arachidonate lipoxygenase metabolites in amniotic fluid of women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1454-60
Effects of the antiprogesterone RU 486 on preterm birth in the rat (Garfield et al). 1987;157:1281-5
Evaluation of 1-deamino-[D-Tyr(Oethyl)^2,Thr^4,Orn^8] vasotocin, an oxytocin antagonist, in animal models of uterine contractility and preterm labor: a new tocolytic agent (Hahn et al). 1987;157:977-82
Increased boy-to-girl ratio in women with preterm labor beginning with contractions (Seki and Kato) (Letter). 1987;157:215-6
The presence or absence of fetal breathing movements as a predictor of outcome in preterm labor (Besinger et al). 1987;157:753-7
Preterm birth at 23 to 26 weeks' gestation: Is active obstetric management justified? (Nwaesei et al). 1987;157:890-7
A prospective random trial of home uterine activity monitoring in pregnancies at increased risk of preterm labor (Iams et al). 1987;157:638-43
Prostaglandin concentrations in amniotic fluid of women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1461-7
Reduction of group B streptococcal maternal and neonatal infections in preterm pregnancies with premature rupture of membranes through a rapid identification test (Morales and Lim). 1987;157:13-6
Risk scoring for preterm labor: Where do we go from here? (Main and Gabbe). 1987;157:789-93 (Clin. opinion)
Second-trimester fetal monitoring and preterm delivery in pregnancies with systemic lupus erythematosus and/or circulating anticoagulant (Druzin et al). 1987;157:1503-10

Ultrasonic prediction of birth weight in preterm fetuses: Which formula is best? (Pielet et al). 1987;157:1411-4

Prevention program

Regional program for prevention of premature birth in northwestern North Carolina (Meis et al). 1987;157:550-6

Progesterone

Effects of the antiprogesterone RU 486 on preterm birth in the rat (Garfield et al). 1987;157:1281-5

Endometrial and myometrial effects of progesterone antagonists in pregnant guinea pigs (Elger et al). 1987;157:1065-74

Estrogen, progesterone, prolactin, prostaglandin E_2, prostaglandin $F_{2\alpha}$, 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$, and 6-keto-prostaglandin $F_{1\alpha}$ gradients across the uterus in women in labor and not in labor (Davidson et al). 1987;157:54-8

In vitro conversion of pregnenolone to progesterone in human term placenta and fetal membranes before and after onset of labor (Khan-Dawood). 1987;157:1333-7

Progesterone synthesis by human amnion, chorion, and decidua at term (Mitchell et al). 1987;157:349-53

Progestin

Continuous estrogen/progestin therapy in menopause (Prough et al). 1987;157:1449-53

Pituitary responses to synthetic corticotropin-releasing hormone: absence of modulatory effects by estrogen and progestin (Liu et al). 1987;157:1387-91

Progestogen; *see also* **Progesterone**

Coagulation effects of oral contraception (Bonnar). 1987;157:1042-8

Endometrial and myometrial effects of progesterone antagonists in pregnant guinea pigs (Elger et al). 1987;157:1065-74

Metabolic effects of oral contraceptives (Gaspard). 1987;157:1029-41

New progestogens in oral contraceptives (Runnebaum and Rabe). 1987;157:1059-63

Progestogen potency in oral contraceptive pills (Gillmer). 1987;157:1048-52

Prolactin

Age-related changes in the female hormonal environment during reproductive life (Musey et al). 1987;157:312-7

Estrogen, progesterone, prolactin, prostaglandin E_2, prostaglandin $F_{2\alpha}$, 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$, and 6-keto-prostaglandin $F_{1\alpha}$ gradients across the uterus in women in labor and not in labor (Davidson et al). 1987;157:54-8

In vivo and in vitro modulation of growth hormone and prolactin of a mixed somatotropic-lactotropic pituitary microadenoma (Muechler et al). 1987;157:453-5

Modulating actions of estradiol on gonadotropin-releasing hormone–stimulated prolactin secretion in postmenopausal individuals (Christiansen et al). 1987;157:320-5

Promethazine

Prevention of pelvic adhesion formation by different modalities of treatment (Fayez and Schneider). 1987;157:1184-8

Proopiomelanocortin

Proopiomelanocortin-related peptides and methionine enkephalin in human follicular fluid: changes during the menstrual cycle (Petraglia et al). 1987;157:142-6

Propranolol

Effects of norepinephrine on lung fluid flow rate in the chronically catheterized fetal lamb (Higuchi et al). 1987;157:986-90

Propylthiouracil

Antithyroid drugs: to breast-feed or not to breast-feed (Cooper). 1987;157:234-5 (Clin. opinion)

Prostacyclin; *see also* **Prostaglandins**

Increased thromboxane biosynthesis in normal pregnancy is mainly derived from platelets (Fitzgerald et al). 1987;157:325-30

Prevention of recurrent idiopathic fetal growth retardation by low-dose aspirin and dipyridamole (Wallenburg and Rotmans). 1987;157:1230-5

Prostaglandins; *see also* **Prostacyclin**

β-Adrenergic receptor agonist infusion increases plasma prostaglandin F levels in pregnant sheep (Casper and Lye). 1987;157:998-1003

Endometrial and myometrial effects of progesterone antagonists in pregnant guinea pigs (Elger et al). 1987;157:1065-74

Estrogen, progesterone, prolactin, prostaglandin E_2, prostaglandin $F_{2\alpha}$, 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$, and 6-keto-prostaglandin $F_{1\alpha}$ gradients across the uterus in women in labor and not in labor (Davidson et al). 1987;157:54-8

A new look at uterine muscle contraction (Carsten and Miller). 1987;157:1303-15 (Curr. dev.)

Ovarian prostaglandin synthase: immunohistochemical localization in the rat (Curry et al). 1987;157:537-43

Prostaglandin concentrations in amniotic fluid of women with intra-amniotic infection and preterm labor (Romero et al). 1987;157:1461-7

Steroid synthetic and prostaglandin metabolizing activity is present in different cell populations from human fetal membranes and decidua (Challis and Vaughan). 1987;157:1474-81

Temporal changes in uterine activity and prostaglandin response to RU 486 in rhesus macaques in late gestation (Haluska et al). 1987;157:1487-95

Treatment of polyhydramnios with prostaglandin synthetase inhibitor (indomethacin) (Cabrol et al). 1987;157:422-6

Protein

The effects of membrane permeability and binding by human serum proteins on steroid influx into the rabbit uterus (Steingold et al). 1987;157:1543-9

Hereditary protein C deficiency during pregnancy (Brenner et al). 1987;157:1160-1

Riboflavin concentration in maternal and cord blood in human pregnancy (Kirshenbaum et al). 1987;157:748-52

Seminal plasma proteins of fertile and infertile men analyzed by two-dimensional electrophoresis (Ayyagari et al). 1987;157:1528-33

Verified self-monitored blood glucose data versus glycosylated hemoglobin and glycosylated serum protein as a means of predicting short-and long-term metabolic control in gestational diabetes (Brustman et al). 1987;157:699-703

Proteolytic enzymes

The effects of proteolytic enzymes on in vitro ovulation in the rabbit (Yoshimura et al). 1987;157:468-75

Protoporphyrin test

Red blood cell zinc protoporphyrin testing for iron-deficiency anemia in pregnancy (Schifman et al). 1987;157:304-7

Pseudocholinesterase

Inhibitory effect of quinidine on plasma pseudocholinesterase activity in pregnant women (Kambam et al). 1987;157:897-9

Psychological adjustment; *see also* **Emotions**
Factors affecting psychological adjustment to a fetal death (Graham et al). 1987;157:254-7
Puerperium
Myocardial infarction in the puerperium (Feldman) (Letter); (Iffy et al) (Reply). 1987;157:515-6
Pulmonary hypoplasia
Fetal pulmonary hypoplasia with hydrothorax (Murayama et al). 1987;157:119-20
Pleural effusions and pulmonary hypoplasia (Castillo et al). 1987;157:1252-5
Ultrasonic ratio of fetal thoracic to abdominal circumference: an association with fetal pulmonary hypoplasia (Johnson et al). 1987;157:764-9

Q

Quinidine
Inhibitory effect of quinidine on plasma pseudocholinesterase activity in pregnant women (Kambam et al). 1987;157:897-9

R

Race
Maternal serum α-fetoprotein screening. III. Pitfalls in evaluating black gravid women (Macri et al). 1987;157:820-2
Racial differences in survival of women with endometrial cancer (Bain et al). 1987;157:914-23
A thirty-year review of maternal mortality in Oklahoma, 1950 through 1979 (Moses et al). 1987;157:1189-94
Rapid identification test
Reduction of group B streptococcal maternal and neonatal infections in preterm pregnancies with premature rupture of membranes through a rapid identification test (Morales and Lim). 1987;157:13-6
Red cells
Red blood cell zinc protoporphyrin testing for iron-deficiency anemia in pregnancy (Schifman et al). 1987;157:304-7
Renal artery
Renal arterial blood flow velocity waveforms in pregnant women (Hata et al). 1987;157:1269-71
Renal function
The nonpredictive value of fetal urinary electrolytes: preliminary report of outcomes and correlation with pathologic diagnosis (Wilkins et al). 1987;157:694-8
Renin
Increased fetoplacental active renin production in pregnancy-induced hypertension (Brar et al). 1987;157:363-7
Residency
Pregnancy among obstetricians: a comparison of births before, during, and after residency (Grunebaum et al). 1987;157:79-83
Stress in residency: proposals for solution (Dilts and Dilts). 1987;157:1093-6 (Clin. opinion)
Respiratory distress syndrome; *see also* **Hyaline membrane disease**
Cholesteryl palmitate as a predictor of fetal lung maturity (Ludmir et al). 1987;157:84-8
Respiratory gases
Cord sampling for the evaluation of oxygenation and acid-base balance in human growth-retarded fetuses (Pardi et al). 1987;157:1221-8
Restriction fragment length polymorphism
Restriction fragment length polymorphisms of the insulin gene hypervariable region in gestational onset diabetes mellitus (Ober et al). 1987;157:1364-8
Resuscitation
A study on intrauterine fetal resuscitation with terbutaline (Patriarco et al). 1987;157:384-7
Rh isoimmunization
Percutaneous umbilical transfusion in severe rhesus isoimmunization: resolution of fetal hydrops (Socol et al). 1987;157:1369-75
Riboflavin
Riboflavin concentration in maternal and cord blood in human pregnancy (Kirshenbaum et al). 1987;157:748-52
Ringer's lactated solution
Prevention of pelvic adhesion formation by different modalities of treatment (Fayez and Schneider). 1987;157:1184-8
Risk
Hormonal contraception: benefits versus risks (Goldzieher). 1987;157:1023-8
Menstrual and reproductive factors and the risk of myocardial infarction in women under 55 years of age (La Vecchia et al). 1987;157:1108-12
Pemphigus in pregnancy: a reevaluation of fetal risk (Metzker and Merlob) (Letter). 1987;157:1012-3
A prospective random trial of home uterine activity monitoring in pregnancies at increased risk of preterm labor (Iams et al). 1987;157:638-43
Recurrent small for gestational age birth: perinatal risks and outcomes (Wolfe et al). 1987;157:288-93
Risk scoring for preterm labor: Where do we go from here? (Main and Gabbe). 1987;157:789-93 (Clin. opinion)
Status of infants at birth and risk for adverse neonatal events and long-term sequelae: a study in low birth weight infants (Luthy et al). 1987;157:676-9
Ritodrine
A randomized trial of ritodrine tocolysis versus expectant management in patients with premature rupture of membranes at 25 to 30 weeks of gestation (Garite et al). 1987;157:388-93
RU 486
Effects of the antiprogesterone RU 486 in normal women. I. Single-dose administration in the midluteal phase (Shoupe et al). 1987;157:1415-20
Effects of the antiprogesterone RU 486 in normal women. II. Administration in the late follicular phase (Shoupe et al). 1987;157:1421-6
Effects of the antiprogesterone RU 486 on preterm birth in the rat (Garfield et al). 1987;157:1281-5
Temporal changes in uterine activity and prostaglandin response to RU 486 in rhesus macaques in late gestation (Haluska et al). 1987;157:1487-95
Rupture of membranes; *see* **Fetal membranes**

S

Salpingostomy
Conservative surgical management of isthmic ectopic pregnancies (Smith et al). 1987;157:604-10
Scalp blade
Breakage of a fetal scalp blade with retention of fragments in the infant's scalp (Nieburg and Gross). 1987;157:441-2
Scalp blood
Intrapartum use of fetal scalp hematocrit in the diagnosis of profound fetal anemia caused by fetomaternal hemorrhage (Herman et al). 1987;157:1182-3

Scalp heat flux and its relationship to scalp blood pH of the fetus (Rudelstorfer et al). 1987;157:372-7
Validity of intrapartum diagnosis of fetal thrombocytopenia (Christiaens and Helmerhorst). 1987;157:864-5

Scalp heat flux
Scalp heat flux and its relationship to scalp blood pH of the fetus (Rudelstorfer et al). 1987;157:372-7

Screening
The "breakfast tolerance test": screening for gestational diabetes with a standardized mixed nutrient meal (Coustan et al). 1987;157:1113-7
Early third-trimester ultrasound screening in gestational diabetes to determine the risk of macrosomia and labor dystocia at term (Bochner et al). 1987;157:703-8
Fetal echocardiographic screening for congenital heart disease: the importance of the four-chamber view (Copel et al). 1987;157:648-55
Maternal serum α-fetoprotein screening: effects of weight adjustment (Kazazian et al) (Letter); (Macri et al) (Reply). 1987;157:782-4
Maternal serum α-fetoprotein screening. III. Pitfalls in evaluating black gravid women (Macri et al). 1987;157:820-2
Screening for genetic anomalies (Washburn) (Letter); (Macri) (Reply). 1987;157:212-3
A screening test (GBS-Test) for urogenital carriage of group B streptococci (Christensen and Christensen). 1987;157:341-2
A sonographic screening method for Down syndrome (Lockwood et al). 1987;157:803-8

Second-look surgery
Another look at the second-assessment procedure for ovarian epithelial carcinoma (Gallup et al). 1987;157:590-6

Seizures
Neonatal seizures after cesarean delivery: higher risk with labor (Spellacy et al). 1987;157:377-9
Spontaneous fetal seizures in utero (Maouris) (Letter). 1987;157:1009-10

Seminal fluid
Seminal plasma proteins of fertile and infertile men analyzed by two-dimensional electrophoresis (Ayyagari et al). 1987;157:1528-33

Sensitivity
Definitions of sensitivity, specificity, false negative results, and false positive results (Kolins) (Letter). 1987;157:517-8

Serum
Cord serum bromide concentration: variation and lack of association with pregnancy outcome (Miller et al). 1987;157:826-30
The effects of membrane permeability and binding by human serum proteins on steroid influx into the rabbit uterus (Steingold et al). 1987;157:1543-9
Elevated maternal serum α-fetoprotein levels and oligohydramnios: poor prognosis for pregnancy outcome (Dyer et al). 1987;157:336-9
Evaluation of serum CA 125 levels in the monitoring of ovarian cancer (Vergote et al). 1987;157:88-92
First-trimester serum levels of the β-subunit of human chorionic gonadotropin in a tubal molar pregnancy (Chase et al). 1987;157:910
Haptoglobin helps diagnose the HELLP syndrome (Poldre). 1987;157:1267
Maternal serum α-fetoprotein screening: effects of weight adjustment (Kazazian et al) (Letter); (Macri et al) (Reply). 1987;157:782-4
Maternal serum α-fetoprotein screening. III. Pitfalls in evaluating black gravid women (Macri et al). 1987;157:820-2
The origin of increased serum iron in pregnancy-induced hypertension (Samuels et al). 1987;157:721-5
Outcome in patients with unusually high maternal serum α-fetoprotein levels (Nelson et al). 1987;157:572-6
A pregnant woman with a high level of naturally occurring immunoglobulin M antibodies to *Toxoplasma gondii* (Konishi). 1987;157:832-3
Serum CA-125 in the evaluation of benign adnexal cysts (Pittaway et al). 1987;157:1426-8
Serum copper level in gynecologic malignancies (Margalioth et al). 1987;157:93-6
Verified self-monitored blood glucose data versus glycosylated hemoglobin and glycosylated serum protein as a means of predicting short- and long-term metabolic control in gestational diabetes (Brustman et al). 1987;157:699-703

Sexual abuse
Configuration of the prepubertal hymen (Pokorny). 1987;157:950-6

Skin fibroblast
The binding and metabolism of low-density lipoprotein by skin fibroblasts of fetuses and newborns with anencephaly (Carr and Parker). 1987;157:1351-5

Small for gestational age
Recurrent small for gestational age birth: perinatal risks and outcomes (Wolfe et al). 1987;157:288-93

Smoking
Caffeine-cigarette interaction on fetal growth (Beaulac-Baillargeon and Desrosiers). 1987;157:1236-40
Cigarette smoking and the risk of female reproductive cancer (Stockwell and Lyman). 1987;157:35-40
The effect of smoking on placental and fetal zinc status (Kuhnert et al). 1987;157:1241-6
The relationship between cadmium, zinc, and birth weight in pregnant women who smoke (Kuhnert et al). 1987;157:1247-51

Society for Gynecologic Investigation
Papers of the Society for Gynecologic Investigation. 1987;157:1333-560

The Society of Perinatal Obstetricians
Transactions of the seventh annual meeting of The Society of Perinatal Obstetricians. 1987;157:627-781

Somatomedin C
Growth hormone, somatomedin C, and nonsuppressible insulin-like activity levels compared in premature, small, average birth weight, and large infants (Samaan et al). 1987;157:1524-8

Somatotropic-lactotropic pituitary microadenoma
In vivo and in vitro modulation of growth hormone and prolactin of a mixed somatotropic-lactotropic pituitary microadenoma (Muechler et al). 1987;157:453-5

Sonography; *see* **Ultrasound**

The South Atlantic Association of Obstetricians and Gynecologists
Transactions of the forty-ninth annual meeting of The South Atlantic Association of Obstetricians and Gynecologists. 1987;157:521-626

Specific gravity
Formulas for fetal weight estimation by ultrasound measurements based on neonatal specific gravities and volumes (Shinozuka et al). 1987;157:1140-5

Specificity
Definitions of sensitivity, specificity, false negative results, and false positive results (Kolins) (Letter). 1987;157:517-8

Spinal cord
The effect of severing the spinal cord of fetal lambs on length of gestation (Nowak et al). 1987;157:464-7
Squamous cell carcinoma
An evaluation of squamous cell carcinoma antigen in patients with cervical squamous cell carcinoma (Senekjian et al). 1987;157:433-9
Statistics
When does a statistical fact become an ethical imperative? (Silver and Minogue). 1987;157:229-33 (Clin. opinion)
Sterilization
Contraception: an overview (Hammerstein). 1987;157:1020-3
Unintended laparotomy associated with laparoscopic tubal sterilization (Franks et al). 1987;157:1102-5
Steroids
The effects of membrane permeability and binding by human serum proteins on steroid influx into the rabbit uterus (Steingold et al). 1987;157:1543-9
Histologic composition of endometrial carcinomas analyzed for steroid receptor content (Soper et al). 1987;157:26-7
Human ovarian oxytocin and steroid hormones (Auletta and Flint) (Letter); (Khan-Dawood and Dawood) (Reply). 1987;157:1010-1
Management of preterm premature rupture of membranes: lack of a national consensus (Capeless and Mead). 1987;157:11-2
A new delivery system for contraceptive steroids (Segal). 1987;157:1090-2
Steroid synthetic and prostaglandin metabolizing activity is present in different cell populations from human fetal membranes and decidua (Challis and Vaughan). 1987;157:1474-81
Stillbirth
Evaluation of a perinatal grief support team (Lake et al). 1987;157:1203-6
Fetal assessment based on fetal biophysical profile scoring: experience in 19,221 referred high-risk pregnancies. II. An analysis of false-negative fetal deaths (Manning et al). 1987;157:880-4
Strength conditioning
Effects of aerobic and strength conditioning on pregnancy outcomes (Hall and Kaufmann). 1987;157:1199-203
Streptococci
Effects of alterations of zinc-to-phosphorus ratios and meconium content on group B *Streptococcus* growth in human amniotic fluid in vitro (Hoskins et al). 1987;157:770-3
Reduction of group B streptococcal maternal and neonatal infections in preterm pregnancies with premature rupture of membranes through a rapid identification test (Morales and Lim). 1987;157:13-6
A screening test (GBS-Test) for urogenital carriage of group B streptococci (Christensen and Christensen). 1987;157:341-2
Stress
Stress in residency: proposals for solution (Dilts and Dilts). 1987;157:1093-6 (Clin. opinion)
Stress incontinence
Urogynecology: comments and caveats (Thiede and Saini). 1987;157:563-8
Stress test
A prospective comparative study of the extended nonstress test and the nipple stimulation contraction stress test (Devoe et al). 1987;157:531-7
A prospective evaluation of nipple stimulation techniques for contraction stress testing (Keegan et al). 1987;157:121-5
Stroke
Coagulation effects of oral contraception (Bonnar). 1987;157:1042-8
Stroma
The effect of insulin on aromatase activity in isolated human endometrial glands and stroma (Randolph et al). 1987;157:1534-9
Suture material
Careful surgical technique can reduce infectious morbidity after cesarean section (Lyon and Richardson). 1987;157:557-62
Symposium
International symposium on contraception. Part 1: oral contraception. 1987;157:1019-63
International symposium on contraception. Part 2: alternative methods of contraception. 1987;157:1064-92
symposium on infection: a complication of obstetric and gynecologic surgery. 1987;157:485-512
Systemic lupus erythematosus
Second-trimester fetal monitoring and preterm delivery in pregnancies with systemic lupus erythematosus and/or circulating anticoagulant (Druzin et al). 1987;157:1503-10
Systolic/diastolic ratio
Uterine artery Doppler velocimetry: the significance of divergent systolic/diastolic ratios (Shulman et al). 1987;157:1539-42

T

Tachycardia
Mexiletine use in pregnancy and lactation (Lownes and Ives). 1987;157:446-7
Ultrasound evaluation of tachycardia-induced hydrops in the fetal lamb (Nimrod et al). 1987;157:655-9
Temperature
Careful surgical technique can reduce infectious morbidity after cesarean section (Lyon and Richardson). 1987;157:557-62
The normal parturient's admission temperature (Acker et al). 1987;157:308-11
Teratology
Disruption of embryonic and fetal development due to preimplantation chemical insults: a critical review (Iannaccone et al). 1987;157:476-84 (Curr. dev.)
Terbutaline
Chronic oral terbutaline tocolytic therapy is associated with maternal glucose intolerance (Main et al). 1987;157:644-7
A study on intrauterine fetal resuscitation with terbutaline (Patriarco et al). 1987;157:384-7
Term Guard uterine activity monitor
A prospective random trial of home uterine activity monitoring in pregnancies at increased risk of preterm labor (Iams et al). 1987;157:638-43
Testosterone
Human chorionic gonadotropin, estriol, and testosterone changes in two pregnancies with hyperreactio luteinalis (Muechler et al). 1987;157:1126-8
α-Thalassemia
Percutaneous ultrasound-guided fetal blood sampling in the management of nonimmune hydrops fetalis (Hsieh et al). 1987;157:44-9

Theca-lutein ovarian cysts associated with homozygous α-thalassemia (Miller et al). 1987;157:912-4

Thawing procedure
Human embryo viability related to freezing and thawing procedures (Testart et al). 1987;157:168-71

Theca-lutein ovarian cyst
Theca-lutein ovarian cysts associated with homozygous α-thalassemia (Miller et al). 1987;157:912-4

Thigh circumference
Fetal weight estimation formulas with head, abdominal, femur, and thigh circumference measurements (Vintzileos et al). 1987;157:410-4

Thoracic circumference
Ultrasonic ratio of fetal thoracic to abdominal circumference: an association with fetal pulmonary hypoplasia (Johnson et al). 1987;157:764-9

Thrombocytopenia
Abnormalities in platelet antiglobulin tests in preeclamptic mothers and their neonates (Samuels et al). 1987;157:109-13
Haptoglobin helps diagnose the HELLP syndrome (Poldre). 1987;157:1267
Validity of intrapartum diagnosis of fetal thrombocytopenia (Christiaens and Helmerhorst). 1987;157:864-5

Thromboembolism; *see also* **Thrombosis**
Coagulation effects of oral contraception (Bonnar). 1987;157:1042-8
Drug prescribing for thromboembolic disease during pregnancy (Greenspoon and Montoro) (Letter). 1987;157:784-5

Thrombosis; *see also* **Thromboembolism**
Hereditary protein C deficiency during pregnancy (Brenner et al). 1987;157:1160-1
Venous thrombosis in patients with cardiac pacemakers and oral contraceptive use (Rao) (Letter). 1987;157:516-7

Thromboxane
Beneficial effects of U-63,557A, a thromboxane synthetase inhibitor, in an ovine model of pregnancy-induced hypertension (Keith et al). 1987;157:199-203
Increased thromboxane biosynthesis in normal pregnancy is mainly derived from platelets (Fitzgerald et al). 1987;157:325-30
Prevention of recurrent idiopathic fetal growth retardation by low-dose aspirin and dipyridamole (Wallenburg and Rotmans). 1987;157:1230-5

Thyrotropin-releasing hormone
Transplacental stimulation of functional and morphologic fetal rabbit lung maturation: effect of thyrotropin-releasing hormone (Devaskar et al). 1987;157:460-4

Tocolysis
Chronic oral terbutaline tocolytic therapy is associated with maternal glucose intolerance (Main et al). 1987;157:644-7
Effects of calcium entry blocker (nicardipine) tocolysis in rhesus macaques: fetal plasma concentrations and cardiorespiratory changes (Ducsay et al). 1987;157:1482-6
Evaluation of 1-deamino-[D-Tyr(Oethyl)^2,Thr^4,Orn^8] vasotocin, an oxytocin antagonist, in animal models of uterine contractility and preterm labor: a new tocolytic agent (Hahn et al). 1987;157:977-82
A randomized trial of ritodrine tocolysis versus expectant management in patients with premature rupture of membranes at 25 to 30 weeks of gestation (Garite et al). 1987;157:388-93

Today contraceptive sponge
Updated pregnancy rates for the Today contraceptive sponge (Edelman and North). 1987;157:1164-5

Toxemia; *see also* **Eclampsia; Preeclampsia**
Hereditary protein C deficiency during pregnancy (Brenner et al). 1987;157:1160-1

Toxoplasma gondii
A pregnant woman with a high level of naturally occurring immunoglobulin M antibodies to *Toxoplasma gondii* (Konishi). 1987;157:832-3

Tracheal fluid
Drug accumulation in lung fluid of the fetal lamb after maternal or fetal administration (Riggs et al). 1987;157:1286-91

Training model
A reusable plastic training model for teaching Papanicolaou smear technique (Beckmann et al). 1987;157:259-60

Transabdominal needling
Transabdominal chorionic villus sampling: a freehand ultrasound-guided technique (Brambati et al). 1987;157:134-7

Transactions
Transactions of the forty-ninth annual meeting of The South Atlantic Association of Obstetricians and Gynecologists. 1987;157:521-626
Transactions of the seventh annual meeting of The Society of Perinatal Obstetricians. 1987;157:627-781

Transfusion
Percutaneous umbilical transfusion in severe rhesus isoimmunization: resolution of fetal hydrops (Socol et al). 1987;157:1369-75
Technical aspects of intravascular intrauterine transfusions: lessons learned from thirty-three procedures (Berkowitz et al). 1987;157:4-9 (Clin. opinion)

Translocation
A novel Y/13 familial translocation (Morris et al). 1987;157:857-8

Transport
Fetal monitoring during emergency obstetric transport (Elliott and Trujillo). 1987;157:245-7

Transurethral ultrasound
Transurethral ultrasound-guided oocyte retrieval for in vitro fertilization (Padilla et al). 1987;157:622-6

Trauma
Erb's palsy and fetal bruising after external cephalic version: case report (Petrikovsky et al). 1987;157:258
Fetal-induced trauma as a cause of antepartum hemorrhage (Eden). 1987;157:830-1

Trial of labor
Previous cesarean delivery and trial of labor (Fribourg) (Letter); (Finley) (Reply). 1987;157:1014-5
When does a statistical fact become an ethical imperative? (Silver and Minogue). 1987;157:229-33 (Clin. opinion)

Triphasics
Phasic approach to oral contraceptives (Hale). 1987;157:1052-8

Triploidy
Sonographic features of the triploid fetus (Lockwood et al). 1987;157:285-7

Trisomy 18
Genetic implications of idiopathic hydramnios (Landy et al). 1987;157:114-7

Trophoblast
HLA antigen expression and induction by γ-interferon in cultured human trophoblasts (Feinman et al). 1987;157:1429-34

Treatment of nonmetastatic gestational trophoblastic disease with oral methotrexate (Barter et al). 1987;157:1166-8

True hermaphrodite

The endocrinologic evaluation of a 45,X true hermaphrodite (Rosen et al). 1987;157:1272-3

Trypsin

Amniotic fluid trypsin and premature rupture of membranes (McGregor et al) (Letter); (Kanayama) (Reply). 1987;157:1316-9

Tubal molar pregnancy

First-trimester serum levels of the β-subunit of human chorionic gonadotropin in a tubal molar pregnancy (Chase et al). 1987;157:910

Tubal patency

Hysterosalpingographic evaluation of tubal patency after ectopic pregnancy (Mitchell et al). 1987;157:618-22

Tubal sterilization

Unintended laparotomy associated with laparoscopic tubal sterilization (Franks et al). 1987;157:1102-5

d-Tubocurarine

The use of fetal neuromuscular blockade during intrauterine procedures (Moise et al). 1987;157:874-9

Tubular enzyme

Increased tubular enzyme excretion in preeclampsia (Goren et al). 1987;157:906-8

Tumor; *see also* **Carcinoma; Neoplasia**

Diagnostic imaging of gynecologic tumors with the monoclonal antibody 791T/36 (Powell et al). 1987;157:28-34

An evaluation of squamous cell carcinoma antigen in patients with cervical squamous cell carcinoma (Señekjian et al). 1987;157:433-9

Multiple primary gynecologic neoplasms (Rose et al). 1987;157:261-7

Serum copper level in gynecologic malignancies (Margalioth et al). 1987;157:93-6

Turner's syndrome

The endocrinologic evaluation of a 45,X true hermaphrodite (Rosen et al). 1987;157:1272-3

Twins

Antenatal diagnosis and management of monoamniotic twins (Rodis et al). 1987;157:1255-7

The length of the human umbilical cord in twin pregnancies (Soernes and Bakke). 1987;157:1229-30

Umbilical blood waveforms in fetal surveillance of twins (Saldana et al). 1987;157:712-5

U

U-63,557A

Beneficial effects of U-63,557A, a thromboxane synthetase inhibitor, in an ovine model of pregnancy-induced hypertension (Keith et al). 1987;157:199-203

Ultrasound

Abdominal pregnancy: magnetic resonance identification with ultrasonographic follow-up of placental involution (Spanta et al). 1987;157:887-9

Antenatal diagnosis with ultrasonography (Shalev and Zuckerman) (Letter). 1987;157:1323

The detection of facial anomalies with ultrasound (Koontz) (Letter); (Pilu) (Reply). 1987;157:1316

Early third-trimester ultrasound screening in gestational diabetes to determine the risk of macrosomia and labor dystocia at term (Bochner et al). 1987;157:703-8

Echocardiographic and anatomic studies of the maternotrophoblastic border during the first trimester of pregnancy (Hustin and Schaaps). 1987;157:162-8

Fetal cerebellar growth unaffected by intrauterine growth retardation: a new parameter for prenatal diagnosis (Reece et al). 1987;157:632-8

Fetal death: diagnosis and management (Pitkin). 1987;157:583-9

Fetal echocardiographic screening for congenital heart disease: the importance of the four-chamber view (Copel et al). 1987;157:648-55

Fetal-induced trauma as a cause of antepartum hemorrhage (Eden). 1987;157:830-1

Formulas for fetal weight estimation by ultrasound measurements based on neonatal specific gravities and volumes (Shinozuka et al). 1987;157:1140-5

The immediate effects of chorionic villus sampling on fetal movements (Boogert et al). 1987;157:137-9

In utero ponderal index as a prognostic factor in the evaluation of intrauterine growth retardation (Yagel et al). 1987;157:415-9

In vitro training model for diagnostic and therapeutic fetal intravascular needle puncture (Timor-Tritsch and Yeh). 1987;157:858-9

Outcome in patients with unusually high maternal serum α-fetoprotein levels (Nelson et al). 1987;157:572-6

Percutaneous ultrasound-guided fetal blood sampling in the management of nonimmune hydrops fetalis (Hsieh et al). 1987;157:44-9

Renal arterial blood flow velocity waveforms in pregnant women (Hata et al). 1987;157:1269-71

Soft tissue nuchal fold in the second-trimester fetus: standards for normal measurements compared with those in Down syndrome (Benacerraf and Frigoletto). 1987;157:1146-9

Sonographic amniotic fluid measurement and fetal growth retardation: a reappraisal (Patterson et al). 1987;157:1406-10

Sonographic diagnosis of a bladder polyp (Jensen and Lynne). 1987;157:1168-9

Sonographic evaluation of the cervix during ovulation induction (Hill et al). 1987;157:1170-4

Sonographic features of the triploid fetus (Lockwood et al). 1987;157:285-7

A sonographic screening method for Down syndrome (Lockwood et al). 1987;157:803-8

Transabdominal chorionic villus sampling: a freehand ultrasound-guided technique (Brambati et al). 1987;157:134-7

Transurethral ultrasound-guided oocyte retrieval for in vitro fertilization (Padilla et al). 1987;157:622-6

Ultrasonic prediction of birth weight in preterm fetuses: Which formula is best? (Pielet et al). 1987;157:1411-4

Ultrasonic ratio of fetal thoracic to abdominal circumference: an association with fetal pulmonary hypoplasia (Johnson et al). 1987;157:764-9

Ultrasound diagnosis of abruptio placentae with fetomaternal hemorrhage (Cardwell). 1987;157:358-9

Ultrasound evaluation of tachycardia-induced hydrops in the fetal lamb (Nimrod et al). 1987;157:655-9

Umbilical artery

Changes in intracardiac Doppler blood flow velocities in fetuses with absent umbilical artery diastolic flow (Reed et al). 1987;157:774-9

Fetal umbilical artery flow velocimetry in postdate pregnancies (Guidetti et al). 1987;157:1521-3

Umbilical artery flow velocity waveforms and placental resistance: the effects of embolization of the umbilical circulation (Trudinger et al). 1987;157:1443-8

Umbilical artery flow velocity waveforms and the placental vascular bed (McCowan et al). 1987;157:900-2
Umbilical blood waveforms in fetal surveillance of twins (Saldana et al). 1987;157:712-5
Uterine and umbilical artery velocimetry during normal labor (Fleischer et al). 1987;157:40-3

Umbilical cord
Cord sampling for the evaluation of oxygenation and acid-base balance in human growth-retarded fetuses (Pardi et al). 1987;157:1221-8
The length of the human umbilical cord in twin pregnancies (Soernes and Bakke). 1987;157:1229-30
The relationships among the fetal biophysical profile, umbilical cord pH, and Apgar scores (Vintzileos et al). 1987;157:627-31
Umbilical cord blood pH and Apgar score as an index of neonatal health (Josten et al). 1987;157:843-8
Umbilical cord size and amniotic fluid volume in prolonged pregnancy (Silver et al). 1987;157:716-20
The umbilical cord twist: origin, direction, and relevance (Lacro et al). 1987;157:833-8

Umbilical transfusion
Percutaneous umbilical transfusion in severe rhesus isoimmunization: resolution of fetal hydrops (Socol et al). 1987;157:1369-75

Umbilical vein
Influence of umbilical vein administration of oxytocin on the third stage of labor: a randomized, double-blind, placebo-controlled study (Chestnut and Wilcox). 1987;157:160-2

Urethral closure pressure
Urogynecology: comments and caveats (Thiede and Saini). 1987;157:563-8

Urine electrolytes
The nonpredictive value of fetal urinary electrolytes: preliminary report of outcomes and correlation with pathologic diagnosis (Wilkins et al). 1987;157:694-8

Urodynamics
Urogynecology: comments and caveats (Thiede and Saini). 1987;157:563-8

Uterine artery
Uterine artery Doppler velocimetry: the significance of divergent systolic/diastolic ratios (Shulman et al). 1987;157:1539-42

Uterus
The cause of uterine softening in pregnancy (Jakobovits et al) (Letter). 1987;157:1013
The effects of membrane permeability and binding by human serum proteins on steroid influx into the rabbit uterus (Steingold et al). 1987;157:1543-9
Estrogen, progesterone, prolactin, prostaglandin E_2, prostaglandin $F_{2\alpha}$, 13,14-dihydro-15-keto-prostaglandin $F_{2\alpha}$, and 6-keto-prostaglandin $F_{1\alpha}$ gradients across the uterus in women in labor and not in labor (Davidson et al). 1987;157:54-8
Evaluation of 1-deamino-[D-Try(Oethyl)^2,Thr^4,Orn^8] vasotocin, an oxytocin antagonist, in animal models of uterine contractility and preterm labor: a new tocolytic agent (Hahn et al). 1987;157:977-82
A new look at uterine muscle contraction (Carsten and Miller). 1987;157:1303-15 (Curr. dev.)
A prospective random trial of home uterine activity monitoring in pregnancies at increased risk of preterm labor (Iams et al). 1987;157:638-43
Simultaneous objective and subjective evaluation of meclofenamate sodium in the treatment of primary dysmenorrhea (Smith and Powell). 1987;157:611-8
Uterine and umbilical artery velocimetry during normal labor (Fleischer et al). 1987;157:40-3

V

Vaccination; *see* **Immunization**

Vaginal bleeding
First-trimester vaginal bleeding and the loss of chromosomally normal and abnormal conceptions (Strobino and Pantel-Silverman). 1987;157:1150-4

Vaginal hysterectomy
Single-dose prophylaxis for vaginal and abdominal hysterectomy (Hemsell et al). 1987;157:498-501

Vaginal mucus
Correlation between chlamydia infection and clinical evaluation, vaginal wet smear, and cervical swab test in female adolescents (Thejls et al). 1987;157:974-6
Preliminary observations on lactoferrin secretion in human vaginal mucus: variation during the menstrual cycle, evidence of hormonal regulation, and implications for infection with *Neisseria gonorrhoeae* (Cohen et al). 1987;157:1122-5

Vaporization
Laser excisional conization and laser vaporization for cervical intraepithelial neoplasia (Anderson) (Letter); (Baggish) (Reply). 1987;157:1322-3

Varicella zoster
Varicella zoster antibody testing in the care of pregnant women exposed to varicella (McGregor et al). 1987;157:281-4

Vascular lesions
Placental bed biopsy technique and vascular lesions (Labarrere) (Letter); (Robertson) (Reply). 1987;157:1320-2
A very rare fetal malformation: the cutaneous widespread vascular hamartomatosis (Arienzo et al). 1987;157:1162-3

Vasoconstriction
Hypoxia-induced fetoplacental vasoconstriction in perfused human placental cotyledons (Howard et al). 1987;157:1261-6

Vasopressin
Circulating neurohypophyseal hormones in anencephalic infants (Oosterbaan and Swaab). 1987;157:117-9
The effect of mild hypoxemia maintained for twenty-four hours on maternal and fetal glucose, lactate, cortisol, and arginine vasopressin in pregnant sheep at 122 to 139 days' gestation (Towell et al). 1987;157:1550-7
Vasopressin-induced bradycardia in fetal and adult sheep is not dependent on an increase in blood pressure (Harper and Rose). 1987;157:448-53

Vasotocin
Evaluation of 1-deamino-[D-Tyr(Oethyl)^2,Thr^4,Orn^8] vasotocin, an oxytocin antagonist, in animal models of uterine contractility and preterm labor: a new tocolytic agent (Hahn et al). 1987;157:977-82

Velocimetry
A classification of hypertension in pregnancy based on Doppler velocimetry (Ducey et al). 1987;157:680-5
Changes in intracardiac Doppler blood flow velocities in fetuses with absent umbilical artery diastolic flow (Reed et al). 1987;157:774-9
Fetal umbilical artery flow velocimetry in postdate pregnancies (Guidetti et al). 1987;157:1521-3

Renal arterial blood flow velocity waveforms in pregnant women (Hata et al). 1987;157:1269-71
Umbilical artery flow velocity waveforms and placental resistance: the effects of embolization of the umbilical circulation (Trudinger et al). 1987;157:1443-8
Umbilical artery flow velocity waveforms and the placental vascular bed (McCowan et al). 1987;157:900-2
Umbilical blood waveforms in fetal surveillance of twins (Saldana et al). 1987;157:712-5
Uterine artery Doppler velocimetry: the significance of divergent systolic/diastolic ratios (Shulman et al). 1987;157:1539-42
Uterine and umbilical artery velocimetry during normal labor (Fleischer et al). 1987;157:40-3

Ventricular tachycardia
Mexiletine use in pregnancy and lactation (Lownes and Ives). 1987;157:446-7

Viability
Human embryo viability related to freezing and thawing procedures (Testart et al). 1987;157:168-71

Vibratory acoustic stimulation; *see* **Acoustic stimulation**

Virus; *see also* **Infection**
Isolation of acquired immunodeficiency syndrome virus from the placenta (Hill et al). 1987;157:10-1
Varicella zoster antibody testing in the care of pregnant women exposed to varicella (McGregor et al). 1987;157:281-4

Vulva
Necrotizing fasciitis of the vulva (Roberts). 1987;157:568-71

W

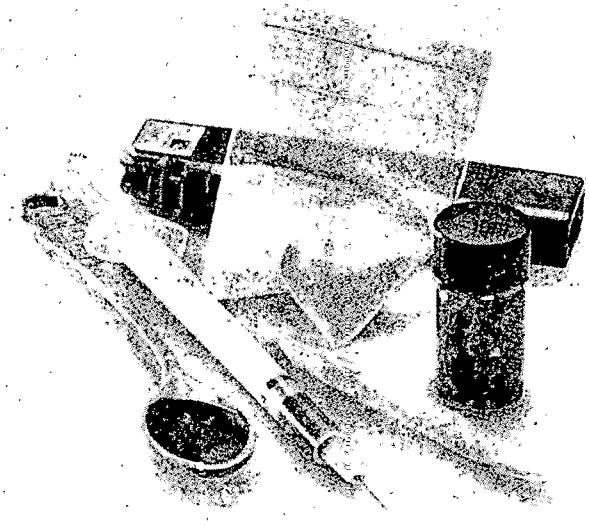
Walking
Postprandial walking exercise in pregnant insulin-dependent (type 1) diabetic women: reduction of plasma lipid levels but absence of a significant effect on glycemic control (Hollingsworth and Moore). 1987;157:1359-63

Waveforms; *see* **Velocimetry**

Weight
Fetal weight estimation formulas with head, abdominal, femur, and thigh circumference measurements (Vintzileos et al). 1987;157:410-4
Formulas for fetal weight estimation by ultrasound measurements based on neonatal specific gravities and volumes (Shinozuka et al). 1987;157:1140-5
Maternal serum α-fetoprotein screening: effects of weight adjustment (Kazazian et al) (Letter); (Macri et al) (Reply). 1987;157:782-4

Weight training
Effects of aerobic and strength conditioning on pregnancy outcomes (Hall and Kaufmann). 1987;157:1199-203

Wharton's jelly
Umbilical cord size and amniotic fluid volume in prolonged pregnancy (Silver et al). 1987;157:716-20



Y

Y chromosome
A novel Y/13 familial translocation (Morris et al). 1987;157:857-8

Z

Zinc
The effect of smoking on placental and fetal zinc status (Kuhnert et al). 1987;157:1241-6
Effects of alterations of zinc-to-phosphorus ratios and meconium content on Group B *Streptococcus* growth in human amniotic fluid in vitro (Hoskins et al). 1987;157:770-3
Magnesium and zinc status during the menstrual cycle (Deuster et al). 1987;157:964-8
Red blood cell zinc protoporphyrin testing for iron-deficiency anemia in pregnancy (Schifman et al). 1987;157:304-7
The relationship between cadmium, zinc, and birth weight in pregnant women who smoke (Kuhnert et al). 1987;157:1247-51

SOME OF YOUR PATIENTS ARE ON DRUGS YOU DIDN'T PRESCRIBE.

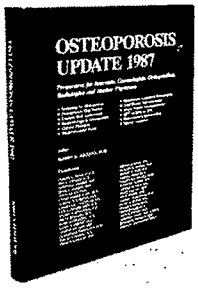
An estimated 20 million Americans are using cocaine. Add to this the number of people using other illegal drugs and the total is truly staggering.

As a physician, you are in a unique position to help reduce this number.

Start with your next patient. While you are examining or treating her, simply ask about drug use. It *is* a medical problem. And knowing about it is the first step toward doing something about it.

Stop letting drugs be your patient's problem alone. *Look* for signs of drug abuse. And *listen* when you ask about patterns of drug use. What you hear could be a plea for help.

You'll never know unless you ask.



PARTNERSHIP FOR A DRUG-FREE AMERICA

Wanted

OB/Gyn house physician, first assistant in OB/Gyn Surgery. Must also be interested in teaching Family Practice Residents. A minimum of 2 years formal training with an unrestricted state license required. Hospital to cover malpractice insurance plus many other benefits. Salary commensurate with training and experience. Call Collect (304) 243-3886.

FACULTY POSITION IN OB/GYN MATERNAL-FETAL MEDICINE

The Wright State University School of Medicine invites applications for a full-time faculty position in maternal-fetal medicine in the department of Obstetrics and Gynecology.

Primary duties will consist of medical student and resident teaching and supervision. The candidate must be licensable to practice medicine in Ohio. Other qualifications include board eligibility or certification in obstetrics and gynecology and completion of a fellowship in maternal-fetal medicine. Academic rank and salary dependent upon qualifications and experience. Please forward curriculum vitae and the names and addresses of three references to John J. Halki, M.D., Ph.D., Chair and Program Director, Department of Obstetrics and Gynecology, Wright State University School of Medicine, 1 Wyoming Street, Dayton, OH 45409. All applications received by December 31, 1987 will be considered; if the position is not filled therefrom, applications will be considered as received until the position is filled. Wright State University is an affirmative action/equal opportunity employer.

FELLOWSHIP IN MATERNAL-FETAL MEDICINE

The University of Oklahoma Tulsa Medical College has a position for a first year Fellow in Maternal-Fetal Medicine for academic year 1988-89. The American Board Approved Fellowship program emphasizes academic excellence in a private practice atmosphere. Applicants must be American Board Eligible or Certified. Qualified applicants should send their C.V. to:

Larry J. D'Angelo, M.D.
6161 South Yale Avenue
Suite 3228
Tulsa, Oklahoma 74136

The University of Oklahoma is an Equal Opportunity Employer

OBSTETRICIAN/ GYNECOLOGIST

West Central Ohio multi-hospital system has several openings for board-eligible OB/GYN physicians. Excellent salary/guarantee plus fringes.

"...Should be in the possession of anyone who lays hand on neonates..."

(Perinatology/Neonatology, review of the last edition)

NEW 4th EDITION!

NEONATAL-PERINATAL MEDICINE: Diseases of the Fetus and Infant

Edited by Avroy A. **Fanaroff,** M.B., F.R.C.P. (Edinburgh), D.C.H. and Richard J. **Martin,** M.B., F.R.A.C.P., F.R.C.P. (Canada); with 99 contributors

"The authors write authoritatively, often incorporating their seasoned judgment and experience rather than presenting a dry and unweighed exposition of the literature...The book should be in the possession of anyone who lays hand on neonates."
(Perinatology/Neonatology, review of the last edition)

Here's complete coverage of disorders and diseases that affect the infant in utero and during the early weeks of life. The emphasis throughout is on pathophysiology, clinical and laboratory manifestations, and prevention and treatment. New discussions explore:
• computers in perinatal medicine • neonatal anesthesia • blood component therapy for neonates • neonatologist's perspective on ROP as well as intraventricular and periventricular hemorrhage • ethical dilemmas in perinatology
July, 1987. Approx. 1,048 pages, 802 illustrations. (01583)
About $85.00 (U.S.); $117.50 (Can.)

Here's what MOSBY'S BOUND VOLUMES can add to your practice!

MOSBY
TIMES MIRROR

Handsomely bound in durable buckram with rich gold stamping, bound journal reference volumes are important to every successful practice.

- gives quick and easy access to important journal articles
- eliminates problems with missing issues or pages
- makes your regular subscription a "working" copy to mark up, tear from, or file
- offers an inexpensive and easy way to guarantee bound reference volumes—prices include shipping

You Must Order Now!
Bound volumes are made up from over-run copies of each journal issue. You never worry about sending out your personal copies. But over-run quantities are limited. We need your order today! Bound volumes are only available to current subscribers and may not be ordered in place of a regular journal subscription. Payment must accompany your order.

Obstetrics And Gynecology Review Course

April 14 - 20 — San Francisco May 11 - 16 — Columbus, Ohio
*Any Six Days — November 29 - December 7, 1988 — Chicago

Now, your only BOARD REVIEW just before Oral Exams is also an excellent update in practice and preview for Written Exams.

OBJECTIVES

- Increase basic knowledge in obstetrics and gynecology
- Improve clinical skills in diagnosis and treatment
- Assist residents and fellows to organize study
- Prepare board candidates to pass board examinations
- Provide practicing surgeons with a review and update

METHODS

- HOME STUDY MATERIALS with questions and answers based on previous examinations
- SEMINAR with projection slides and syllabus
- LABORATORY with microscopic slides
- PRACTICE EXAMS with oral and written parts

*Nov. 29 - Dec. 4 (live); Dec. 5 - 7 (Video replay of Nov. 29 - Dec. 4). Any six days will complete the program.

*The faculty was outstanding. The most pleasant thing was learning a tremendous amount, not only from world-famous authorities but from people who are relatively unknown as well."**

*"Accomodations were comfortable...."**

GOALS AND LOCATION: The cours be held in the San Francisco Bay Are in Ohio as regional reviews for both wr and oral exams. Home-study question sent upon registration. Your best value repeat the seminar for $315 or $90 the before and in the same area as the oral e Topics and faculty are upgraded for program. It is also an excellent updat practicing gynecologists. Meetings will the best combinations of luxury hotels bargain rates. Our previous programs at tons, Hyatts, Marriotts, Adam's Mark Meridians have been at or below $70 si and $84 double.

*"...and those little extras...."**

LOWEST AIR FARES AND HOTEL: have negotiated group discount air **below super saver rates.** Please wait fo structions before buying travel tickets.

*"...the most education for the money."**

FEES AND C.M.E. CREDITS:
- C.M.E. Credit: 60 hours
- Residents and Fellows: $420
- Practicing Ob/Gyns: $630
- Repeating first time within 3 years: $
- Repeating other times within 3 years
- **Add 10% to payment after Mar. 31,**
- Attendees not in course hotels add $8
- $50.00 will reserve your position.
- Most home study materials will be m after half the registration fee is recei
- Additional materials will be received completion of home study assignmer

"...home study material was extremely help

CANCELLATIONS: Refunds subject to fee, will be made until the seminar beg
- Cancellations after mailing most study material will require retention o of the fee.

*"...remarkably complete and pleasant."**.

21-and 28-day regimens

ORTHO-NOVUM 777

norethindrone/ethinyl estradiol TRADEMARK Tablets

Each white tablet contains 0.5 mg norethindrone and 0.035 mg ethinyl estradiol. Each light peach tablet contains 0.75 mg norethindrone and 0.035 mg ethinyl estradiol. Each peach tablet contains 1 mg norethindrone and 0.035 mg ethinyl estradiol. Each green tablet in 28-day regimen contains inert ingredients.

IMPORTANT NOTE—This information is a BRIEF SUMMARY of the complete prescribing information provided with the product and therefore should not be used as the basis for prescribing the product. This summary was prepared by deleting from the complete prescribing information certain text, tables, and references. The physician should be thoroughly familiar with the complete prescribing information before prescribing the product.

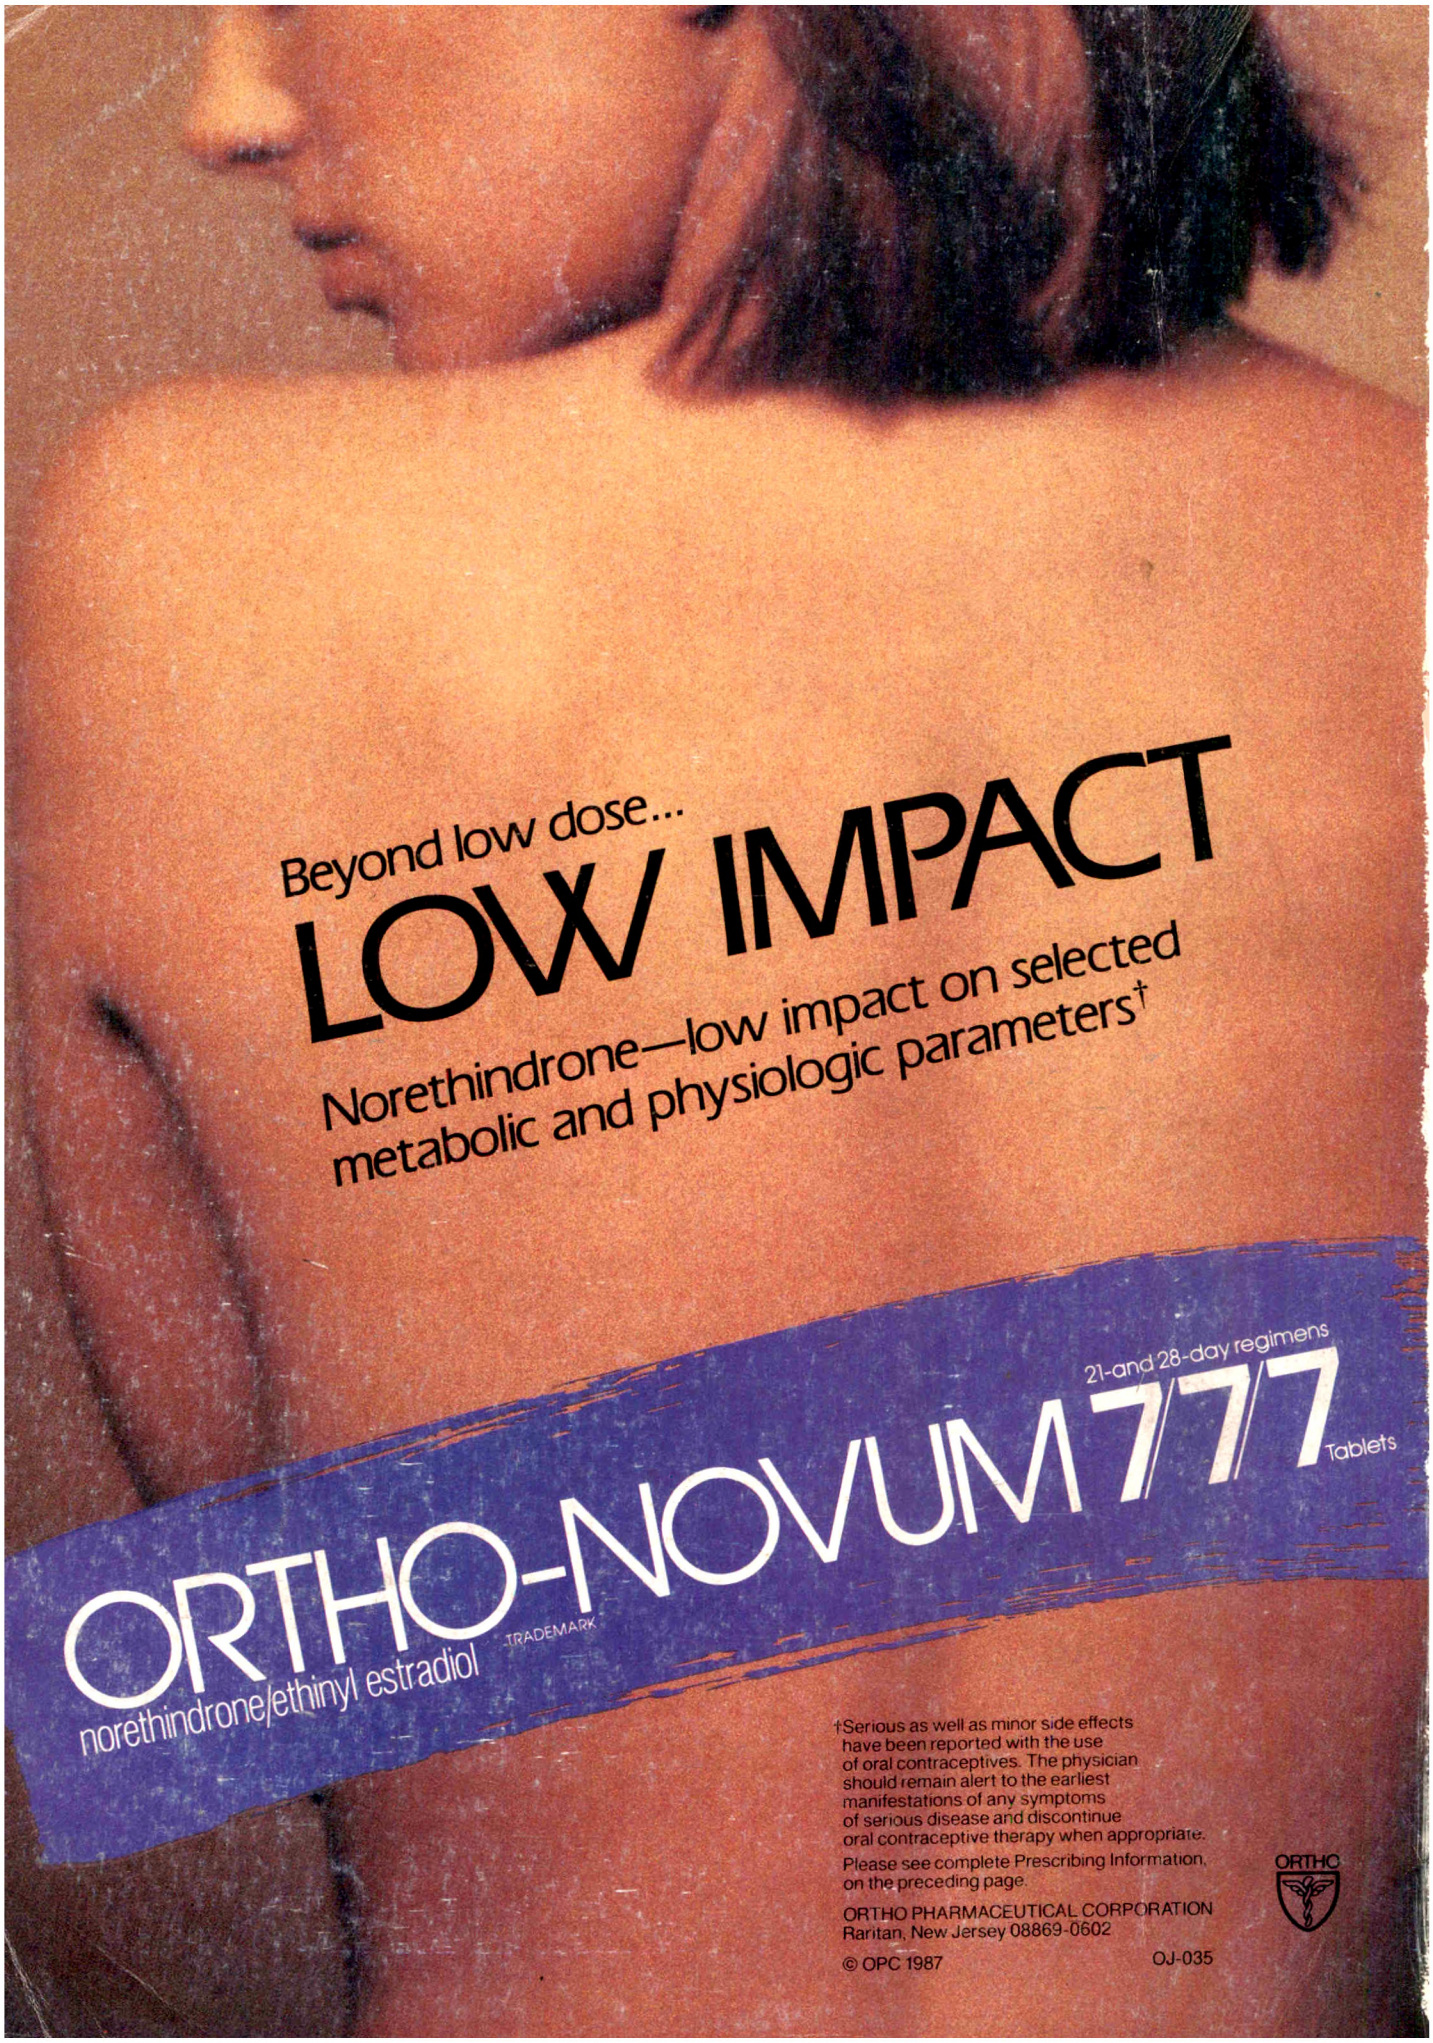
INDICATIONS AND USAGE: PREVENTION OF PREGNANCY.

DOSE-RELATED RISK OF THROMBOEMBOLISM FROM ORAL CONTRACEPTIVES: Two studies have shown a positive association between the dose of estrogens in oral contraceptives and the risk of thromboembolism. For this reason, it is prudent and in keeping with good principles of therapeutics to minimize exposure to estrogen. The oral contraceptive product prescribed for any given patient should be that product which contains the least amount of estrogen that is compatible with an acceptable pregnancy rate and patient acceptance. It is recommended that new acceptors of oral contraceptives be started on preparations containing .05 mg or less of estrogen.

CONTRAINDICATIONS: Oral contraceptives should not be used in women with any of the following conditions: 1. Thrombophlebitis or thromboembolic disorders. 2. A past history of deep vein thrombophlebitis or thromboembolic disorders. 3. Cerebral vascular or coronary artery disease. 4. Known or suspected carcinoma of the breast. 5. Known or suspected estrogen-dependent neoplasia. 6. Undiagnosed, abnormal genital bleeding. 7. Oral contraceptive tablets may cause fetal harm when administered to a pregnant woman. Oral contraceptive tablets are contraindicated in women who are pregnant. If the patient becomes pregnant while taking this drug, the patient should be apprised of the potential hazard to the fetus (see WARNINGS, No. 5). 8. Benign or malignant liver tumor which developed during the use of oral contraceptives or other estrogen-containing products.

WARNINGS

Cigarette smoking increases the risk of serious cardiovascular side effects from oral contraceptive use. This risk increases with age and with heavy smoking (15 or more cigarettes per day) and is quite marked in women over 35 years of age. Women who use oral contraceptives should be strongly advised not to smoke.



The use of oral contraceptives is associated with increased risk of several serious conditions including thromboembolism, stroke, myocardial infarction, hepatic adenoma, gallbladder disease, hypertension. Practitioners prescribing oral contraceptives should be familiar with the following information relating to these risks.

1. THROMBOEMBOLIC DISORDERS AND OTHER VASCULAR PROBLEMS. An increased risk of thromboembolic and thrombotic disease associated with the use of oral contraceptives is well established. Four principal studies in Great Britain and three in the United States have demonstrated an increased risk of fatal and nonfatal venous thromboembolism and stroke, both hemorrhagic and thrombotic. These studies estimate that users of oral contraceptives are 4 to 11 times more likely than nonusers to develop these diseases without evident cause. Overall excess mortality due to pulmonary embolism or stroke is on the order of 1.0 to 3.5 deaths annually per 100,000 users and increases with age. **CEREBROVASCULAR DISORDERS:** In a collaborative American study of cerebrovascular disorders in women with and without predisposing causes, it was estimated that the risk of hemorrhagic stroke was 2.0 times greater in users than in nonusers and the risk of thrombotic stroke was 4.0 to 9.5 times greater in users than in nonusers. A prospective study conducted in Great Britain estimated that former users have a risk for all cerebrovascular disease 2.6 times greater than that of nonusers. This risk remained elevated for at least six years after last oral contraceptive use. A prospective study conducted in the United States found that past use of oral contraceptives was associated with increased risk of subarachnoid hemorrhage, the relative risk being 5.3. There was also some evidence from this study that the degree of risk may be related to duration of oral contraceptive use. **MYOCARDIAL INFARCTION:** An increased risk of myocardial infarction associated with the use of oral contraceptives has been reported confirming a previously suspected association. These studies, conducted in the United Kingdom, found, as expected, that the greater the number of underlying risk factors for coronary artery disease (cigarette smoking, hypertension, hypercholesterolemia, obesity, diabetes, history of preeclamptic toxemia), the higher the risk of developing myocardial infarction, regardless of whether the patient was an oral contraceptive user or not. Oral contraceptives, however, were found to be a clear additional risk factor. The annual excess case rate (increased risk) of myocardial infarction (fatal and nonfatal) in oral contraceptive users was estimated to be approximately 7 cases per 100,000 women users in the 30-39 age group and 67 cases per 100,000 women users in the 40-44 age group. In terms of relative risk, it has been estimated that oral contraceptive users who do not smoke (smoking is considered a major predisposing condition to myocardial infarction) are about twice as likely to have a fatal myocardial infarction as nonusers who do not smoke. Oral contraceptive users who are also smokers have about a 5-fold increased risk of fatal infarction compared to users who do not smoke, but about a 10- to 12-fold increased risk compared to nonusers who do not smoke. Furthermore, the amount of smoking is also an important factor. In determining the importance of these relative risks, however, the baseline rates for various age groups must be given serious consideration. The importance of other predisposing conditions mentioned above in determining relative and absolute risks has not as yet been quantified; it is quite likely that the same synergistic action exists, but perhaps to a lesser extent. A study suggests that some increased risk of myocardial infarction in oral contraceptive users persists following discontinuation of oral contraceptives and that the degree of the residual risk is related to the duration of the past use. **Risk of Dose:** In an analysis of data derived from several national adverse reaction reporting systems, British investigators concluded that the risk of thromboembolism including coronary thrombosis is directly related to the dose of estrogen used in oral contraceptives. Preparations containing 100 mcg or more of estrogen were associated with a higher risk of thromboembolism than those containing 50-80 mcg of estrogen. Their analysis did suggest, however, that the quantity of estrogen may not be the sole factor involved. This finding has been confirmed in the United States. Careful epidemiological studies to determine the degree of thromboembolic risk associated with progestogen-only oral contraceptives have not been performed. Cases of thromboembolic disease have been reported in women using these products, and they should not be presumed to be free of excess risk. The risk of thromboembolic and thrombotic disorders, in both users and nonusers of oral contraceptives, increases with age. Oral contraceptives are, however, an independent risk factor for these events. **ESTIMATE OF EXCESS MORTALITY FROM CIRCULATORY DISEASES:** A large prospective study carried out in the United Kingdom estimated the mortality rate per 100,000 women per year from diseases of the circulatory system for users and nonusers of oral contraceptives according to age, smoking habits, and duration of use. The overall excess death rate annually from circulatory diseases for oral contraceptive users was estimated to be 20 per 100,000 (ages 15-34—5/100,000; ages 35-44—33/100,000; ages 45-49—140/100,000), the risk being concentrated in older women, in those with a long duration of use, and in cigarette smokers. It was not possible, however, to examine the interrelationships of age, smoking, and duration of use, nor to compare the effects of continuous versus intermittent use. Although the study showed a 10-fold increase in death due to circulatory diseases in users for five or more years, all of these deaths occurred in women 35 or older. Until larger numbers of women under 35 with continuous use for five or more years are available, it is not possible to assess the magnitude of the relative risk for this younger age group. This study reports that the increased risk of circulatory disease mortality may persist after the pill is discontinued. Another study published at the same time confirms a previously reported increase of mortality in pill users from cardiovascular disease. The study concluded that the mortality associated with all methods of birth control is low and below that associated with childbirth, with the exception of oral contraceptives in women over 40 who smoke. (The rates given for pill only/smokers for each age group are for smokers as a class. For "heavy" smokers [more than 15 cigarettes a day], the rates given would be about double; for "light" smokers [less than 15 cigarettes a day], about 50 percent.) The mortality associated with oral contraceptive use in nonsmokers over 40 is higher than with any other method of contraception in that age group. The lowest mortality is associated with the condom or diaphragm backed up by early abortion. The risk of thromboembolic and thrombotic disease associated with oral contraceptives increases with age after approximately age 30 and, for myocardial infarction, is further increased by hypertension, hypercholesterolemia, obesity, diabetes, or history of preeclamptic toxemia and especially by cigarette smoking. The risk of myocardial infarction in oral contraceptive users is substantially increased in women age 40 and over, especially those with other risk factors. The physician and the patient should be alert to the earliest manifestations of thromboembolic and thrombotic disorders (e.g., thrombophlebitis, pulmonary embolism, cerebrovascular insufficiency, coronary occlusion, retinal thrombosis, and mesenteric thrombosis). Should any of these occur or be suspected, the drug should be discontinued immediately. A four- to six-fold increased risk of postsurgery thromboembolic complications has been reported in oral contraceptive users. If feasible, oral contraceptives should be discontinued at least four weeks before surgery of a type associated with an increased risk of thromboembolism or prolonged immobilization. 2. OCULAR LESIONS. There have been reports of neuro-ocular lesions such as optic neuritis or retinal thrombosis associated with the use of oral contraceptives. Discontinue oral contraceptive medication if there is unexplained, sudden or gradual, partial or complete loss of vision; onset of proptosis or diplopia; papilledema; or retinal vascular lesions and institute appropriate diagnostic and therapeutic measures. 3. CARCINOMA. Long-term continuous administration of either natural or synthetic estrogen in certain animal species increases the frequency of carcinoma of the breast, cervix, vagina, and liver. Certain synthetic progestogens, none currently contained in oral contraceptives, have been noted to increase the incidence of mammary nodules, benign and malignant, in dogs. In humans, three case control studies have reported an increased risk of endometrial carcinoma associated with the prolonged use of exogenous estrogen in postmenopausal women. One publication reported on the first 21 cases submitted by physicians to a registry of cases of adenocarcinoma of the endometrium in women under 40 on oral contraceptives. Of the cases found in women without predisposing risk factors or adenocarcinoma of the endometrium (e.g., irregular bleeding at the time oral contraceptives were first given, polycystic ovaries), nearly all occurred in women who had used a sequential oral contraceptive. These products are no longer marketed. No evidence has been reported suggesting an increased risk of endometrial cancer in users of conventional combination or progestogen-only oral contraceptives. Several studies have found no increases in breast cancer in women taking oral contraceptives or estrogens. One study, however, while also noting no overall increased risk of breast cancer in women treated with oral contraceptives, found an excess risk in the subgroups of oral contraceptive users with documented benign breast disease. A reduced occurrence of benign breast tumors in users of oral contraceptives has been well-documented. In summary, there is at present no confirmed evidence from human studies of an increased risk of cancer associated with oral contraceptives. Close clinical surveillance of all women taking oral contraceptives is, nevertheless, essential. In all cases of undiagnosed persistent or recurrent abnormal vaginal bleeding, appropriate diagnostic measures should be taken to rule out malignancy. Women with a strong family history of breast cancer or who have breast nodules, fibrocystic disease or abnormal mammograms should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. 4. HEPATIC TUMORS. Benign hepatic adenomas have been found to be associated with the use of oral contraceptives. One study showed that oral contraceptive formulations with high hormonal potency were associated with a higher risk than lower potency formulations and use of oral contraceptives with high hormonal potency and age over 30 years may further increase the woman's risk of hepatocellular adenoma. Although benign, hepatic adenomas may rupture and may cause death through intra-abdominal hemorrhage. This has been reported in short-term as well as long-term users of oral contraceptives. Two studies relate risk with duration of use of the contraceptive, the risk being much greater after four or more years of oral contraceptive use. While hepatic adenoma is a rare lesion, it should be considered in women presenting abdominal pain and tenderness, abdominal mass or shock. Cases of hepatocellular carcinoma, although rare, have been reported in women taking oral contraceptives. Retrospective studies conducted in the United States and Britain report an increased risk of hepatocellular carcinoma in oral contraceptive users, particularly with increased duration of use. 5. USE IN OR IMMEDIATELY PRECEDING PREGNANCY, BIRTH DEFECTS IN OFFSPRING, AND MALIGNANCY IN FEMALE OFFSPRING. The use of female sex hormones—both estrogenic and progestational agents—during early pregnancy may seriously damage the offspring. It has been shown that females exposed in utero to diethylstilbestrol, a nonsteroidal estrogen, have an increased risk of developing in later life a form of vaginal or cervical cancer that is ordinarily extremely rare. This risk has been estimated to be on the order of 1 to 4 in 1000 exposures. Although there is no evidence at the present time that oral contraceptives further enhance the risk of developing this type of malignancy, such patients should be monitored with particular care if they elect to use oral contraceptives instead of other methods of contraception. Furthermore, a high percentage of such exposed women (from 30 to 90%) have been found to have epithelial changes of the vagina and cervix. Although these changes are histologically benign, it is not known whether this condition is a precursor of vaginal malignancy. Male children so exposed may develop abnormalities of the urogenital tract. Although similar data are not available with the use of other estrogens, it cannot be presumed that they would not induce similar changes. An increased risk of congenital anomalies, including heart defects and limb defects, has been reported with the use of sex hormones, including oral contraceptives, in pregnancy. One case control study has estimated a 4.7-fold increase in risk of limb-reduction defects in infants exposed in utero to sex hormones (oral contraceptives, hormonal withdrawal tests for pregnancy or attempted treatment for threatened abortion). Some of these exposures were very short and involved only a few days of treatment. The data suggest that the risk of limb-reduction defects in exposed fetuses is somewhat less than one in 1000 live births. In the past, female sex hormones have been used during pregnancy in an attempt to treat threatened or habitual abortion. There is considerable evidence that estrogens are ineffective for these indications, and there is no evidence from well-controlled studies that progestogens are effective for these uses. There is some evidence that triploidy and possibly other types of polyploidy are increased among abortuses from women who become pregnant soon after ceasing oral contraceptives. Embryos with these anomalies are virtually always aborted spontaneously. Whether there is an overall increase in spontaneous abortion of pregnancies conceived soon after stopping oral contraceptives is unknown. It is recommended that for any patient who has missed two consecutive periods, pregnancy should be ruled out before continuing the contraceptive regimen. If the patient has not adhered to the prescribed schedule, the possibility of pregnancy should be considered at the time of the first missed period (or after 45 days from the last menstrual period if the progestogen-only oral contraceptives are used), and further use of oral contraceptives should be withheld until pregnancy has been ruled out. If pregnancy is confirmed, the patient should be apprised of the potential risks to the fetus and the advisability of continuation of the pregnancy should be discussed in the light of these risks. It is also recommended that women who discontinue oral contraceptives with the intent of becoming pregnant use an alternate form of contraception for a period of time before attempting to conceive. Many clinicians recommend three months although no precise information is available on which to base this recommendation. The administration of progestogen-only or progestogen-estrogen combinations to induce withdrawal bleeding should not be used as a test of pregnancy. 6. GALLBLADDER DISEASE. Studies report an increased risk of surgically confirmed gallbladder disease in users of oral contraceptives and estrogens. In one study, an increased risk appeared after two years of use and doubled after four or five years of use. In one of the other studies, an increased risk was apparent between six and twelve months of use. 7. CARBOHYDRATE AND LIPID METABOLIC EFFECTS. A decrease in glucose tolerance has been observed in a significant percentage of patients on oral contraceptives. For this reason, prediabetic and diabetic patients should be carefully observed while receiving oral contraceptives. An increase in triglycerides and total phospholipids has been observed in patients receiving oral contraceptives. The clinical significance of this finding remains to be defined. 8. ELEVATED BLOOD PRESSURE. An increase in blood pressure has been reported in patients receiving oral contraceptives. In some women hypertension may occur within a few months of beginning oral contraceptive use. In the first year of use, the prevalence of women with hypertension is low in users and may be no higher than that of a comparable group of nonusers. The prevalence in users increases, however, with longer exposure, and in the fifth year of use is two and a half to three times the reported prevalence in the first year. Age is also strongly correlated with the development of hypertension in oral contraceptive users. Women who previously have had hypertension during pregnancy may be more likely to develop elevation of blood pressure when given oral contraceptives. Hypertension that develops as a result of taking oral contraceptives usually returns to normal after discontinuing the drug. 9. HEADACHE. The onset or exacerbation of migraine or development of headache of a new pattern which is recurrent, persistent, or severe, requires discontinuation of oral contraceptives and evaluation of the cause. 10. BLEEDING IRREGULARITIES. Breakthrough bleeding, spotting, and amenorrhea are frequent reasons for patients discontinuing oral contraceptives. In breakthrough bleeding, as in all cases of irregular bleeding from the vagina, nonfunctional causes should be borne in mind. In undiagnosed persistent or recurrent abnormal bleeding from the vagina, adequate diagnostic measures are indicated to rule out pregnancy or malignancy. If pathology has been excluded, time or a change to another formulation may solve the problem. Changing to an oral contraceptive with a higher estrogen content, while potentially useful in minimizing menstrual irregularity, should be done only if necessary since this may increase the risk of thromboembolic disease. Women with a past history of oligomenorrhea or secondary amenorrhea or young women without regular cycles may have a tendency to remain anovulatory or to become amenorrheic after discontinuation of oral contraceptives. Women with these preexisting problems should be advised of this possibility and encouraged to use other contraceptive methods. Postuse anovulation, possibly prolonged, may also occur in women without previous irregularities. 11. ECTOPIC PREGNANCY. Ectopic as well as intrauterine pregnancy may occur in contraceptive failures. 12. BREAST FEEDING. Oral contraceptives given in the postpartum period may interfere with lactation. There may be a decrease in the quantity and quality of the breast milk. Furthermore, a small fraction of the hormonal agents in oral contraceptives has been identified in the milk of mothers receiving these drugs. The effects, if any, on the breast-fed child have not been determined. If feasible, the use of oral contraceptives should be deferred until the infant has been weaned. **PRECAUTIONS: General:** 1. A complete medical and family history should be taken prior to the initiation of oral contraceptives. The pretreatment and periodic physical examinations should include special reference to blood pressure, breasts, abdomen and pelvic organs, including Papanicolaou smear and relevant laboratory tests. As a general rule, oral contraceptives should not be prescribed for longer than one year without another physical examination being performed. 2. Under the influence of estrogen-progestogen preparations, preexisting uterine leiomyomata may increase in size. 3. Patients with a history of psychic depression should be carefully observed and the drug discontinued if depression recurs to a serious degree. Patients becoming significantly depressed while taking oral contraceptives should stop the medication and use an alternate method of contraception in an attempt to determine whether the symptom is drug-related. 4. Oral contraceptives may cause some degree of fluid retention. They should be prescribed with caution, and only with careful monitoring, in patients with conditions which might be aggravated by fluid retention, such as convulsive disorders, migraine syndrome, asthma, or cardiac or renal insufficiency. 5. Patients with a past history of jaundice during pregnancy have an increased risk of recurrence of jaundice while receiving oral contraceptive therapy. If jaundice develops in any patient receiving such drugs, the medication should be discontinued. 6. Steroid hormones may be poorly metabolized in patients with impaired liver function and should be administered with caution in such patients. 7. Oral contraceptive users may have disturbances in normal tryptophan metabolism which may result in a relative pyridoxine deficiency. The clinical significance of this is yet to be determined. 8. Serum folate levels may be depressed by oral contraceptive therapy. Since the pregnant woman is predisposed to the development of folate deficiency and the incidence of folate deficiency increases with increasing gestation, it is possible that if a woman becomes pregnant shortly after stopping oral contraceptives, she may have a greater chance of developing folate deficiency and complications attributed to this deficiency. **INFORMATION FOR THE PATIENT: (See Patient Package Insert). DRUG INTERACTIONS:** Reduced efficacy and increased incidence of breakthrough bleeding have been associated with concomitant use of rifampin. A similar association has been suggested with barbiturates, phenylbutazone, phenytoin sodium, ampicillin, griseofulvin, and tetracycline. **DRUG/LABORATORY TEST INTERACTIONS:** The pathologist should be advised of oral contraceptive therapy when relevant specimens are submitted. Certain endocrine and liver function tests and blood components may be affected by estrogen-containing oral contraceptives: a. Increased sulfobromophthalein retention. b. Increased prothrombin and factors VII, VIII, IX and X; decreased antithrombin 3; increased norepinephrine-induced platelet aggregability. c. Increased thyroid-binding globulin (TBG) leading to increased circulating total thyroid hormone, as measured by protein-bound iodine (PBI), T4 by column, or T4 by radioimmunoassay. Free T3 resin uptake is decreased, reflecting the elevated TBG; free T4 concentration is unaltered. d. Decreased pregnanediol excretion. e. Reduced response to metyrapone test. **CARCINOGENESIS, MUTAGENESIS, IMPAIRMENT OF FERTILITY, PREGNANCY, NURSING MOTHERS: See CONTRAINDICATIONS and WARNINGS. ADVERSE REACTIONS:** An increased risk of the following serious adverse reactions has been associated with the use of oral contraceptives (see WARNINGS): Thrombophlebitis. Pulmonary embolism. Coronary thrombosis. Cerebral thrombosis. Cerebral hemorrhage. Hypertension. Gallbladder disease. Liver tumors. Congenital anomalies. There is evidence of an association between the following conditions and the use of oral contraceptives, although additional confirmatory studies are needed: Mesenteric thrombosis. Neuro-ocular lesions, e.g., retinal thrombosis and optic neuritis. The following adverse reactions have been reported in patients receiving oral contraceptives and are believed to be drug-related: Nausea and/or vomiting, usually the most common adverse reactions, occur in approximately 10% or less of patients during the first cycle. Other reactions, as a general rule, are seen much less frequently or only occasionally. Gastrointestinal symptoms (such as abdominal cramps and bloating). Breakthrough bleeding. Spotting. Change in menstrual flow. Dysmenorrhea. Amenorrhea during and after treatment. Temporary infertility after discontinuance of treatment. Edema. Chloasma or melasma which may persist. Breast changes: tenderness, enlargement, and secretion. Change in weight (increase or decrease). Change in cervical erosion and cervical secretion. Possible diminution in lactation when given immediately postpartum. Cholestatic jaundice. Migraine. Increase in size of uterine leiomyomata. Rash (allergic). Mental depression. Reduced tolerance to carbohydrates. Vaginal candidiasis. Change in corneal curvature (steepening). Intolerance to contact lenses. The following adverse reactions have been reported in users of oral contraceptives, and the association has been neither confirmed nor refuted: Premenstrual-like syndrome. Cataracts. Changes in libido. Chorea. Changes in appetite. Cystitis-like syndrome. Headache. Nervousness. Dizziness. Hirsutism. Loss of scalp hair. Erythema multiforme. Erythema nodosum. Hemorrhagic eruption. Vaginitis. Porphyria. Impaired renal function. Hemolytic uremic syndrome. **OVERDOSAGE:** Serious ill effects have not been reported following acute ingestion of large doses of oral contraceptives by young children. Overdosage may cause nausea, and withdrawal bleeding may occur in females.

Revised 2/87

ORTHO PHARMACEUTICAL CORPORATION

ORTHO

Beyond low dose...
LOW IMPACT
Norethindrone—low impact on selected metabolic and physiologic parameters†
21-and 28-day regimens
ORTHO-NOVUM 7/7/7 Tablets
TRADEMARK
norethindrone/ethinyl estradiol
†Serious as well as minor side effects have been reported with the use of oral contraceptives. The physician should remain alert to the earliest manifestations of any symptoms of serious disease and discontinue oral contraceptive therapy when appropriate.
Please see complete Prescribing Information on the preceding page.
